Associated cardiovascular problems also need to be evaluated, including the possibility of aortic regurgitation and mitral valve prolapse with associated regurgitation. Many patients are already on treatment with beta-adrenergic blockers to slow the progression of aortic regurgitation. These medications should be continued during pregnancy if any degree of aortic dilation is present. Periodic echocardiographic surveillance every 6 to 8 weeks is recommended to monitor the mother's aortic root size, with the interval dependent on the initial echocardiographic findings. Any chest pain should be promptly evaluated to rule out dissection. During labor and delivery, pushing should be avoided, with an assisted second stage if necessary. In patients with a dilated aorta, delivery should be accomplished in a tertiary care center where experienced cardiothoracic surgical expertise is available.

Cardiomyopathies

(See Chapters 23, 25, 66, and 66.)

Dilated Cardiomyopathy

Patients with idiopathic dilated cardiomyopathy usually are counseled not to have a pregnancy if the ejection fraction is lower than 40%.³⁸ Because angiotensin-converting enzyme (ACE) inhibitors are contraindicated in pregnancy, ventricular function must be assessed without this drug. Careful echocardiographic evaluation should be performed before pregnancy. Exercise testing also may be helpful, because women with ejection fractions of 40% to 50% may not tolerate pregnancy well if they have a poor functional aerobic capacity. Symptomatic patients who proceed with a pregnancy may need hydralazine for afterload reduction, bed rest, and low-dose diuretics for heart failure. Early delivery also may be necessary. In one study of 36 pregnancies in 32 women with dilated cardiomyopathy, 14 of 36 pregnancies (39%) were complicated by at least one maternal cardiac event.³⁹ Moderate or severe left ventricular dysfunction was the main determinant of adverse maternal cardiac outcomes, and the 16-month event-free survival was worse in pregnant than in nonpregnant women.

Peripartum Cardiomyopathy

Peripartum cardiomyopathy (PPCM) is a life-threatening disease associated with left ventricular dysfunction occurring during the last months of pregnancy or within 5 months of delivery in previously healthy women. Frequently, uncertainty exists about whether cases fulfill diagnostic criteria, or whether the disorder represents a preexisting cardiomyopathy that became apparent during pregnancy. Cardiac imaging (usually with transthoracic echocardiography) is essential to establish the diagnosis.

The precise incidence of PPCM is unknown but appears to be approximately 1 in 2500 to 1 in 4000 in the United States and around 1 in 300 in Haiti.⁴⁰ The higher incidence in some countries suggests the influence of environmental risk factors or a common genetic mutation. Known risk factors include multiparity, black race, older maternal age, and particularly preeclampsia. In a retrospective study of 123 women with PPCM,⁴¹ a history of hypertension was obtained in 43% of the patients, and twin pregnancies were reported in 13%. Consistent with earlier studies, most patients (75%) presented in the first month postpartum, perhaps suggesting an autoimmune cause rather than a preexisting cardiomyopathy exacerbated by the pregnancy.

The etiology and pathophysiology are poorly understood, but inflammation may play a role, because serum markers of inflammation (C-reactive protein, interferon- γ [IFN- γ] and interleukin-6) are elevated in many patients. Autoimmune processes, apoptosis, and endothelial dysfunction also play a role.

Recent studies suggest that PPCM is a vascular disease, with cardiac angiogenic imbalance and an excess of antiangiogenic signaling that is accentuated by preeclampsia. The placenta in late pregnancy secretes vascular endothelial growth factor (VEGF) inhibitors such as soluble Flt1 (sFlt1), and plasma levels of sFlt1 have been shown to be abnormally high in women with PPCM. In addition,

preeclampsia and multiple gestations also are characterized by marked elevation of sFlt1 levels, which may explain why they are important risk factors for the development of PPCM. Host susceptibility with inadequate local proangiogenic defenses in the heart also may be a contributory factor, and animal models have demonstrated rescue of the cardiomyopathy by proangiogenic therapies.⁴²

Other reports suggest that unbalanced peripartum oxidative stress leads to the proteolytic cleavage of the nursing hormone prolactin, with the resultant formation of a 16-kDa subform that is a potent antiangiogenic, proapoptotic, and proinflammatory agent.⁴³ These effects may drive the disease by affecting the endothelium, as well as the cardiac vasculature and cardiac myocyte function. This hypothesis has led to a potential therapeutic strategy with blockade of prolactin by bromocriptine, a dopamine D₂ receptor agonist. This treatment has been shown to prevent the disease in experimental animal models and appeared to be successful in small pilot studies with respect to prevention and treatment in patients.^{44,45} Because prolactin acts as a “scavenger” for thrombin, however, its elimination by bromocriptine may increase the risks of thromboembolism, and concomitant heparin anticoagulation has been advised.⁴⁵ Randomized trials are necessary to determine safe and effective treatment strategies.

In other respects, the treatment of PPCM is the same as for other forms of congestive heart failure (see Chapter 25), except that ACE inhibitors and angiotensin receptor–blocking agents are contraindicated in pregnancy. Sodium and fluid restriction is important. Hydralazine, beta blockers, and digoxin have been used and are safe, and diuretics may decrease preload and relieve symptoms, although they may potentially reduce placental blood flow and therefore must be used cautiously.⁴⁶ Aldosterone antagonists may have antiandrogenic effects on the fetus and should be avoided. Nitrates and inotropes also may be necessary in more severe cases. Intracardiac thrombus and embolism are common, and consideration should be given to anticoagulation with heparin in patients with an ejection fraction lower than 35%. Early fetal delivery may be necessary in women requiring hospitalization for heart failure, but the timing and mode of delivery depend on the maternal clinical status. Cesarean section is the preferred mode of delivery in hemodynamically unstable patients. Temporary circulatory support, with either an intra-aortic balloon pump or a left ventricular assist device, or extracorporeal membrane oxygenation may be necessary in those with cardiogenic shock. Cardiac transplantation may be considered in those cases refractory to mechanical circulatory support.

The role of endomyocardial biopsy is controversial, because a histologic classification to confirm the diagnosis is lacking. The procedure may be considered and performed by interventionists with considerable experience. Immunosuppressive treatment can be considered in patients with proven myocarditis.

Normalization of ventricular function occurs in approximately 23% to 54% of patients with PPCM⁴⁷ and appears to be more likely if the ejection fraction is greater than 30% at the time of diagnosis. Most physicians counsel against a second pregnancy, even if the ventricular function does return to normal, because PPCM will recur in approximately 30% of cases.⁴⁸ Such recurrence may result in significant clinical deterioration and even death.⁴⁶

Hypertrophic Cardiomyopathy

A wide spectrum of anatomic and hemodynamic abnormalities has been documented in hypertrophic cardiomyopathy, including left ventricular outflow tract obstruction, mitral regurgitation, arrhythmias, and diastolic dysfunction. Some patients are asymptomatic, with minimal hemodynamic disturbance; others exhibit profound functional limitation, with marked hemodynamic perturbations. A careful personal history, review of family history, an electrocardiogram, exercise testing, and transthoracic echocardiography should precede counseling about the advisability of a pregnancy. The prospective parents should be informed about the autosomal dominant inheritance pattern, which has variable penetrance. Currently, more than 200 genetic mutations have been identified, and genetic counseling and family screening are appropriate before pregnancy is contemplated.

Most women with hypertrophic cardiomyopathy tolerate pregnancy well. The decrease in afterload that might exacerbate the outflow gradient is largely offset by the maternal increase in plasma volume. Medications such as beta blockers, which alleviate the outflow tract obstruction, may be continued throughout pregnancy, but the dose may need to be increased. Patients with significant symptoms before pregnancy (usually related to severe left ventricular outflow tract obstruction) may not do well and become hemodynamically unstable. Common symptoms include palpitation, angina, and breathlessness. In a study of 127 women with 271 pregnancies, 36 women (28.3%) reported cardiac symptoms but 90% were symptomatic before pregnancy.⁴⁹ Heart failure occurred postpartum in two women, but there were no maternal deaths. Arrhythmia-related deaths in pregnancy have been reported, however. Low-dose diuretics may be helpful to treat heart failure in pregnancy, but care must be taken to avoid volume depletion, which exacerbates the left ventricular outflow gradient. Meticulous attention should be paid to hemodynamics at the time of delivery. Epidural anesthesia and spinal block should be avoided in case of hypotension, and blood losses should be promptly replaced. The Valsalva maneuver should be avoided, and the second stage should be facilitated as necessary. Cesarean section is indicated for obstetric reasons only.

Coronary Artery Disease

Coronary artery disease (see Chapters 51 to 55) is uncommon in women of childbearing age but may occur, particularly in the setting of diabetes and tobacco abuse. Acute myocardial infarction is rare, but with the rise in maternal age and increasing number of high-risk women who become pregnant, the incidence is increasing. When it occurs, pregnancy increases the maternal mortality rate to an estimated 5% to 10%. The most common cause is coronary artery dissection,⁵⁰ and the most common site is in the left anterior descending coronary artery. This tends to occur more commonly in the time around delivery or during the postpartum period and may relate to the presence of hypertension and also to the altered elastin and collagen synthesis induced by the hormonal changes of pregnancy.

When an acute coronary syndrome occurs, the patient should be immediately referred to a skilled intervention center for diagnostic angiography with a consideration of percutaneous coronary intervention and stenting.³⁴ This management strategy is preferable to thrombolysis, because of the increased likelihood of coronary dissection during pregnancy. Tissue plasminogen activator does not cross the placenta but may cause placental bleeding and should be avoided unless the situation is life-threatening. Drug-eluting stents require prolonged dual antiplatelet therapy and should be avoided. Data on clopidogrel are limited, so this agent should be used only when absolutely necessary (e.g., after stenting) and for the shortest duration possible.

A U.S. population-based study⁵¹ has reported 44 deaths related to acute myocardial infarction for the years 2000 to 2002, for a case fatality rate of 5.1%. The odds of acute myocardial infarction were 30-fold higher for women 40 years of age and older than for women younger than 20 years. The odds were more than five times higher for black women aged 35 years and older. Thrombus formation also may occur without atherosclerotic disease, presumably as a consequence of the clotting diathesis of pregnancy.

Hypertension

Hypertension (see Chapters 43 and 44) is the most common medical problem in pregnancy and is a well-recognized contributor to maternal morbidity and mortality. The definition is based on absolute systolic blood pressure values greater than 140 mm Hg or diastolic values greater than 90 mm Hg. The different types of hypertension seen in pregnancy are defined in Table 78-3.⁵² Gestational hypertension is distinguished from preeclampsia by the lack of proteinuria. Approximately 50% of patients will develop preeclampsia, however, so close monitoring is warranted. It develops in approximately 25% of patients with chronic hypertension. Preeclampsia is a

TABLE 78-3 Classification of Hypertension in Pregnancy

HYPERTENSION TYPE	DEFINITION/DESCRIPTION
Chronic hypertension	Hypertension (blood pressure ≥ 140 mm Hg systolic or ≥ 90 mm Hg diastolic) present before pregnancy or that is diagnosed before the 20th week of gestation
Gestational hypertension	New hypertension with a blood pressure of 140/90 mm Hg on two separate occasions, without proteinuria, arising de novo after the 20th week of pregnancy Blood pressure normalizes by 12 weeks post partum
Preeclampsia superimposed on chronic hypertension	Increased blood pressure above the patient's baseline, a change in proteinuria, or evidence of end-organ dysfunction
Preeclampsia-eclampsia	Proteinuria (protein excretion >0.3 g during 24 hours or grade ++ in two urine samples) in addition to new hypertension Edema no longer included as diagnostic criterion because of poor specificity In the absence of proteinuria, the disease should nevertheless be suspected when increased blood pressure is associated with headache, blurred vision, abdominal pain, low platelets, or abnormal liver enzymes

From Gifford RW, August PA, Cunningham G, et al: Report of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy. *Am J Obstet Gynecol* 183:S1, 2000.

more worrisome development and tends to occur more commonly in primiparous women and those with twin pregnancies and diabetes. Frank hypertension, when it occurs, usually does not develop until the second half of gestation, accompanied by new-onset significant proteinuria (excretion of 3 g of protein over 24 hours). The cause is not entirely clear, but the pathomechanism may involve endothelial dysfunction causing abnormal remodeling of the placental spiral arteries. Hypertension is just one feature of the diffuse endothelial dysfunction, which is associated with vasospasm, reduced end-organ perfusion, and activation of the coagulation cascade.

Although antihypertensive medications are effective in treating chronic hypertension that has worsened during pregnancy, they are not effective in preventing preeclampsia. When preeclampsia develops, bed rest usually is initiated, with salt restriction and close monitoring, and magnesium sulfate often is administered in an effort to prevent eclamptic seizures and to prolong the pregnancy, thereby facilitating fetal maturity. Urgent delivery usually is necessary, however, after which the blood pressure usually normalizes rapidly.

The treatment of other types of hypertension in pregnancy involves bed rest, salt restriction, and antihypertensive medications. Beta blockers, particularly labetalol (see later under Cardiovascular Drug Therapy) (Table 78-4), have been used with good effect, although a long safety record has been accrued with methyldopa, which has no adverse effect on mother or baby.

Coarctation of the aorta needs to be considered (Fig. 78-4).

Arrhythmias

Because of the physiologic changes of pregnancy, the heart may be more vulnerable to arrhythmias (see Chapters 35 to 38) during this time. Potential contributing factors include the increase in preload, causing more myocardial irritability; increased heart rate, which may affect the refractory period; fluid and electrolyte shifts; and changes in catecholamine levels. Worsening of arrhythmias is not a consistent feature, however, and many women with a past history of tachycardia may not notice any change in the frequency of symptoms, and some

TABLE 78-4 Cardiovascular Drugs in Pregnancy

DRUG	POTENTIAL FETAL SIDE EFFECTS
Amiodarone	Goiter, hypothyroidism and hyperthyroidism, IUGR
Angiotensin-converting enzyme inhibitors	Contraindicated; IUGR, oligohydramnios, renal failure, abnormal bone ossification; FDA class X
Aspirin	Baby aspirin not harmful
Beta blockers	Relatively safe; IUGR, neonatal bradycardia, and hypoglycemia
Calcium channel blockers	Relatively safe; few data; concern regarding uterine tone at the time of delivery
Digoxin	Safe; no adverse effects
Flecainide	Relatively safe; limited data; used to treat fetal arrhythmias
Hydralazine	Safe; no major adverse effects
Furosemide	Safe; caution regarding maternal hypovolemia and reduced placental blood flow
Lidocaine	Safe; high doses may cause neonatal central nervous system depression
Methyldopa	Safe; considered by some to be the drug of choice for hypertension in pregnancy
Procainamide	Relatively safe; limited data; has been used to treat fetal arrhythmias, no major fetal side effects
Propafenone	Limited data
Quinidine	Relatively safe; rarely associated with neonatal thrombocytopenia; minimal oxytocic effect
Warfarin	Fetal embryopathy, placental and fetal hemorrhage, central nervous system abnormalities; FDA class X

IUGR = intrauterine growth retardation.

FIGURE 78-4 Magnetic resonance imaging scan of the heart obtained in a 34-year-old woman with severe coarctation of the aorta (near interruption), with multiple very large collateral vessels. She had had two previous pregnancies with preeclampsia, and the coarctation had gone unnoticed.

even improve. The presenting symptom complex may be difficult to separate from the normal symptoms of pregnancy, including a sensation of fast heartbeat and skipped beats, which most commonly are supraventricular ectopics. The general approach should include taking a careful history, looking for any precipitating causes, and ruling out any concomitant medical problems (e.g., thyroid disease) by performing appropriate laboratory tests, such as complete blood count, electrolyte level measurement, and thyroid function determination. The clinical examination may help define whether the arrhythmia occurs in the setting of a normal heart or identify any underlying organic heart disease. If any doubt remains after this examination, a transthoracic echocardiogram should be obtained. In the absence of underlying cardiac disease, pharmacologic treatment should be administered if the patient is symptomatic or if the arrhythmia poses a risk to mother or baby. In general, supraventricular and ventricular ectopic beats require no therapy. With underlying organic disease, the precipitating cause should be treated, if possible, and if the arrhythmia does not resolve, appropriate medical therapy should be initiated.

Atrial arrhythmias are the most common, and treatment generally is the same as for nonpregnant women, but with added concern about medication effects on the fetus (see [Table 78-4](#)). Intravenous adenosine usually is the drug of choice for atrial reentry tachycardia if vagal maneuvers fail. For drug therapy in general, the lowest dose necessary to treat the arrhythmia should be administered, with periodic evaluation of whether it is necessary to continue treatment. Atrial fibrillation usually is an indication of underlying structural heart disease. If the arrhythmia is unresponsive to medical therapy, electrical cardioversion may be performed and usually is not harmful to the fetus. Some investigators have recommended use of fetal monitoring during elective cardioversion, in case transient fetal bradycardia occurs. Catheter ablation is considered during pregnancy only when absolutely necessary, owing to the high radiation exposure incurred with concomitant fluoroscopic guidance, although advances in the procedure have greatly minimized the need for fluoroscopy and lead shielding can protect the fetus.

Premature ventricular complexes are common during pregnancy and usually require no treatment. Ventricular tachycardia is rare but may be a consequence of ischemic heart disease or cardiomyopathy. The treatment depends on the rate of tachycardia and the hemodynamic status of the mother. The choices of medications are listed in [Table 78-4](#); electrical cardioversion should be performed in patients with hemodynamic compromise.

CARDIOVASCULAR DRUG THERAPY

When administration of cardiovascular drugs is being contemplated during pregnancy, the U.S. Food and Drug Administration (FDA) classification of these drugs must be considered. The reader is referred to more detailed information in this regard (see also [Chapter 9](#)). Category X drugs are those for which fetal abnormalities have been demonstrated in animal or human studies and are therefore contraindicated (e.g., warfarin). Most cardiovascular drugs are classified as category C, which means that animal studies have revealed adverse fetal effects, but controlled data in women are lacking. A medication should be given only if the benefits outweigh the potential risk to the fetus. Principles to be considered include the use of drugs with the longest safety record, the use of the lowest dose and shortest duration necessary, and avoidance of a multidrug regimen, if possible. All of these issues need to be reviewed carefully with the prospective mother at the time of pre-pregnancy counseling. A list of cardiovascular medications that may potentially be considered in pregnancy is presented in [Table 78-4](#).

Aspirin

Aspirin crosses the placenta, and a recognized concern is its effect on fetal prostaglandins, which may potentially cause closure of the fetal ductus arteriosus. Baby aspirin (81 mg), however, has been used safely in pregnancy without premature closure of the fetal duct. An

aspirin regimen may be useful adjunctive therapy when the mother has a mechanical valve prosthesis and should be considered after the first trimester to help prevent valve thrombosis.²⁴

Amiodarone

Amiodarone and its iodine component cross the placenta and may cause neonatal goiter. The risks and benefits of its use, however, need to be balanced. If this agent has proved effective in controlling serious maternal arrhythmias, it may be safer for the mother to continue its use during pregnancy.

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors are contraindicated in pregnancy because they are associated with abnormal renal development in the fetus, as well as oligohydramnios and intrauterine growth retardation.

Beta-Adrenergic Receptor Blockers

Beta-adrenergic receptor blockers have been used extensively during pregnancy for treatment of arrhythmias, hypertrophic cardiomyopathy, and hypertension. These drugs cross the placenta but are not teratogenic. Of concern, however, is the potential risk of fetal growth retardation, neonatal bradycardia, and hypoglycemia associated with use of these agents. Atenolol has been implicated more commonly than some of the other drugs in this class. From a practical perspective, however, although the risk-to-benefit ratio needs to be considered, beta blockers have been used safely during pregnancy, although it is recommended that fetal growth be monitored more carefully.

Calcium Channel Blockers

Calcium channel blockers have been used to treat both arrhythmias and hypertension. Data regarding the use of these agents in pregnancy are limited. Most experience probably has been accumulated with verapamil, and no major adverse fetal effects have been recorded. Diltiazem and nifedipine also have been used, but studies are limited.

Digoxin

Digoxin has been used during pregnancy for many decades, and although it does cross the placenta, no adverse fetal effects with its use during pregnancy have been reported.

Diuretics

Diuretics, most commonly furosemide, may be used to treat congestive heart failure during pregnancy and sometimes for the treatment of hypertension. Aggressive use of diuretics, however, may impair placental blood flow and fetal growth.

Warfarin

Warfarin usually is contraindicated in the first trimester because it may cause fetal embryopathy (see earlier under [Mechanical Prostheses and Anticoagulant Treatment](#)). In some high-risk situations, however, the mother and her physician will recognize that the safer approach is to continue warfarin therapy, particularly when the maternal dose is 5 mg or lower. Concern arises in the third trimester, before labor and delivery, in relation to immaturity of the fetal liver, which does not metabolize warfarin as rapidly as the maternal liver: After discontinuation of warfarin, reversal of anticoagulation occurs more rapidly in the mother but may take up to 1 week in the fetus. Vaginal delivery when the fetus is anticoagulated is contraindicated because of the risk of fetal hemorrhage, so heparin must be substituted well before labor is anticipated.

CONTRACEPTION

For female patients with cardiac disease, appropriate contraceptive advice should be given before they become sexually active.⁵³ This is particularly important for adolescents with congenital heart disease, who, like others in this age group, often become sexually active in

their early teens. For some patients, pregnancy may carry a high risk of morbidity and even death.⁵⁴ Detailed advice about various contraceptive methods and their effectiveness is appropriate, and each patient should understand the relative risks and benefits of each modality.⁵⁵ The approach should be individualized, with consideration of the likelihood of compliance.⁵³

Barrier Contraception

Used correctly, male and female condoms help protect against sexually transmitted disease but require some dexterity to ensure effectiveness. Even when these devices are used appropriately, however, the recognized failure rate is approximately 15 pregnancies/100 woman-years of use. The decision to use a barrier method, therefore, depends on how critical it is for the woman to avoid pregnancy and on compliance and the ability to use a condom correctly.

Intrauterine Devices

Intrauterine devices (IUDs) constitute an effective form of contraception, with failure rates of approximately 3 pregnancies/100 woman-years. Complications include infection and arrhythmia at the time of insertion. A vasovagal response occurring in a patient with pulmonary arterial hypertension, such as Eisenmenger syndrome, could be life-threatening, and many physicians therefore avoid use of IUDs in such patients. Progesterone-eluting IUDs are more effective than earlier devices in preventing pregnancy and also act on the cervical mucus to prevent fertilization.

Oral Contraceptives

Combination estrogen-progesterone oral preparations have an extremely low failure rate, and for this reason, coupled with ease of use, these agents are widely taken. For the woman with heart disease, however, an important concern is the associated increased risk of venous thromboembolism, atherosclerosis, hyperlipidemia, hypertension, and ischemic heart disease, particularly in patients who are older than 40 years and those who smoke. In addition, patients with congenital heart disease who have cyanosis, atrial fibrillation or flutter, mechanical prosthetic heart valves, or a Fontan circulation probably should avoid estrogen-containing preparations. Patients with impaired ventricular function from any cause (probably specifically those with an ejection fraction less than 40%) or with a history of any previous thromboembolic event should avoid estrogen.

Progesterone-only contraceptives are less reliable than combined preparations, with failure rates of 2 to 5 pregnancies/100 woman-years. The pill must be taken at the same time every day for optimum efficacy. The paucity of data on adverse effects on the cardiovascular system limits firm conclusions, but these agents probably are safe for most women with heart disease.

Alternative Combined Hormonal Preparations

Other contraceptive modalities include vaginal rings and transdermal patches. The vaginal ring is a once-monthly device that is removed after 3 weeks. Transdermal patches containing estrogen and progesterone also are available, as well as an injectable preparation, both of which have similar efficacy rates.

Depot Progesterone

Injectable progesterone, given once every 3 months, is effective and is an option for patients in whom compliance with oral medication regimens may be difficult. Fluid retention and irregular menstruation may be problematic, but cardiovascular contraindications are otherwise the same as those for progesterone. Subdermal implants, which are inserted into the arm, also are available.

Emergency Contraception

In the United States, emergency oral contraception (the "morning after" pill) contains the progestin levonorgestrel. The reported failure rate is less than 1%.

Tubal Sterilization

Tubal sterilization may be performed laparoscopically or through a laparotomy approach. For patients with tenuous cardiac hemodynamics, some risk of cardiac instability is likely, and cardiac anesthesia may be preferable. For patients with pulmonary hypertension or Fontan physiology, general anesthesia may be hazardous, and insufflation of the abdomen may elevate the diaphragm, thereby contributing to unstable cardiorespiratory function. Tubal sterilization can be safely accomplished with the use of an intrafallopian plug, which is inserted endoscopically.⁵⁶

FUTURE PERSPECTIVES

Appropriate pregnancy counseling for women with cardiac disease is problematic. Few physicians have expertise or training in the management of such patients, particularly those with congenital heart disease. Few evidence-based guidelines are available, and many questions remain unanswered. Although successful pregnancy is possible in most women with heart disease, does the volume load cause subtle long-term deterioration in ventricular function in those with limited cardiac reserve?⁵⁷ What is the ideal management strategy for women with mechanical valve prostheses? The potential to use pregnancy history to identify young women at increased risk for cardiovascular disease is important, but would these patients benefit from preventive treatment options that would otherwise not have been prescribed?³ These continued uncertainties emphasize the need for multicenter research initiatives to elucidate the many issues that remain.

GUIDELINES

Pregnancy and Heart Disease

Carole A. Warnes and Thomas H. Lee

Recommendations for the management of heart disease in pregnancy appear in various American College of Cardiology/American Heart Association (ACC/AHA) guidelines. These include guidelines on valvular heart disease,¹ atrial fibrillation,² and stroke.³ The European Society of Cardiology has published guidelines for the management of pregnancy and heart disease that are comprehensive in scope and include a detailed review of the anticoagulant management of patients with mechanical prosthetic heart valves.⁴ The American College of Chest Physicians also has published guidelines on antithrombotic therapy and pregnancy.⁵

Atrial Fibrillation

Atrial fibrillation is rare during pregnancy and usually is associated with another underlying cause, such as mitral stenosis, congenital heart disease, or hyperthyroidism. Diagnosis and treatment of the underlying condition causing the dysrhythmia are of utmost importance. Antithrombotic therapy is recommended for all pregnant women with atrial fibrillation. The type of therapy should be chosen with regard to the stage of pregnancy (**Table 78G-1**).⁶ The new oral thrombin antagonists such as dabigatran have shown fetotoxicity with high doses and should not be used.⁴ The ventricular rate should be controlled with digoxin, a calcium channel antagonist, or a beta blocker. Direct-current cardioversion can be performed without fetal damage in women who become hemodynamically unstable because of atrial fibrillation. Administration of quinidine or procainamide is a reasonable approach for cardioversion in pregnant women with atrial fibrillation who are hemodynamically

TABLE 78G-1 ACC/AHA Recommendations for Management of Atrial Fibrillation (AF) During Pregnancy

CLASS	INDICATION	LEVEL OF EVIDENCE
Class I (indicated)	Control the rate of ventricular response with digoxin, a beta blocker, or a calcium channel antagonist.	C
	Perform electrical cardioversion in patients who become hemodynamically unstable because of the dysrhythmia.	C
	Administer antithrombotic therapy (anticoagulant or aspirin) throughout pregnancy to all patients with AF (except those with lone AF).	C
Class IIb (weak supportive evidence)	Attempt pharmacologic cardioversion by administration of quinidine, procainamide, or sotalol in hemodynamically stable patients who develop AF during pregnancy.	C
	Administer heparin to patients with risk factors for thromboembolism during the first trimester and last month of pregnancy. Unfractionated heparin may be administered either by continuous intravenous infusion in a dose sufficient to prolong the activated partial thromboplastin time to 1.5 to 2 times the control (reference) value or by intermittent subcutaneous injection in a dose of 10,000 to 20,000 units every 12 hours, adjusted to prolong the midinterval (6 hours after injection) activated partial thromboplastin time to 1.5 times control. Limited data are available to support the subcutaneous administration of low-molecular-weight heparin for this indication.	C
	Administer an oral anticoagulant during the second trimester to patients at high thromboembolic risk.	C

stable. Sotalol, flecainide, and propafenone may be used in severe cases.⁴

Valvular Disease

Many women with valvular heart disease can be successfully managed throughout pregnancy, labor, and delivery with conservative medical measures. Symptomatic or severe valvular lesions should be identified and repaired before conception and pregnancy whenever possible.

Mitral Stenosis

Pregnant women with mild to moderate mitral stenosis almost always can be managed with judicious use of diuretics and beta blockade. A cardioselective beta blocker may prevent deleterious effects of epinephrine blockade on myometrial tissue. Women with severe mitral stenosis should be considered for percutaneous balloon mitral valvotomy before conception, if possible. Percutaneous balloon valvotomy is a reasonable option for women who become severely symptomatic during pregnancy.

Mitral Regurgitation

Mitral regurgitation usually can be managed medically with diuretics and vasodilator therapy. If surgery is required, repair is always preferred.

Aortic Stenosis

Pregnant women with mild obstruction and normal left ventricular systolic function can be managed conservatively throughout pregnancy. Those with severe obstruction or symptoms should be advised to delay conception until aortic stenosis can be corrected. Women with severe aortic stenosis in whom symptoms develop may require either early delivery of the baby or percutaneous aortic balloon valvotomy or surgery before delivery.⁴

Aortic Regurgitation

Isolated aortic regurgitation usually can be managed with diuretics and vasodilator therapy when needed. Surgery during pregnancy should be contemplated only for control of refractory symptoms.

Endocarditis Prophylaxis

The guidelines do not recommend routine antibiotic prophylaxis in patients with valvular heart disease undergoing uncomplicated vaginal delivery or cesarean section unless infection is suspected. For high-risk patients, such as those with cyanotic heart disease, prosthetic heart valves, or a previous history of endocarditis, antibiotics are considered optional.⁷

Supraventricular Tachycardias

Premature atrial beats, which are commonly observed during pregnancy, are generally benign and well tolerated. In patients with mild symptoms and structurally normal hearts, no treatment other than reassurance should be provided. All commonly used antiarrhythmic drugs cross the placental barrier to some extent, so antiarrhythmic drug therapy should be reserved for symptomatic patients or those in whom the tachycardia causes hemodynamic compromise (**Table 78G-2**).⁷

Catheter ablation should be recommended for women with symptomatic tachyarrhythmias before they contemplate pregnancy. Many antiarrhythmic drugs can be continued safely during pregnancy, but the risk-to-benefit ratio must always be a consideration. Catheter ablation is the procedure of choice for drug-refractory, poorly tolerated supraventricular tachycardia. If needed, it should be performed in the second trimester.

Stroke

Pregnancy increases the risk for stroke and complicates the selection of acute and preventive treatments. Guidelines for acute treatment have not yet been established. Recommendations for stroke prevention in pregnant women made by the AHA and American Stroke Association³ focus on anticoagulation and antiplatelet strategies (**Table 78G-3**), which are similar to those for management of valvular heart disease during pregnancy.

Hypertension

The European Society of Cardiology addressed the management of hypertension in its 2011 Guidelines (**Table 78G-4**).⁸

Anticoagulation

The 2006 ACC/AHA guidelines on valvular heart disease emphasize the importance of pre-pregnancy counseling on anticoagulation strategies before pregnancy and the need for meticulous and frequent monitoring of the anticoagulation regimen once pregnancy occurs. The guidelines reflect the high complication rates in pregnant women with mechanical prosthetic heart valves, particularly those with older-generation mitral prostheses. A menu of suggested options is presented in **Table 78G-5**. Use of heparin in the first trimester with consideration of transition to warfarin after fetal organogenesis is complete is a common approach. Heparin throughout pregnancy also is an option versus warfarin throughout pregnancy in high-risk cases. The choice of anticoagulant should be individualized after detailed discussion with the prospective mother. After the 36th week of pregnancy, transition from warfarin to heparin is recommended in anticipation of labor. These guidelines are currently being updated. No consensus has emerged on the ideal management strategy for women with mechanical prosthetic heart valves, owing to the paucity

TABLE 78G-2 ACC/AHA Recommendations for Treatment Strategies for Supraventricular Tachycardias During Pregnancy

INDICATION	CLASS [with level of evidence]			
	CLASS I (INDICATED)	CLASS IIA (STRONG SUPPORTIVE EVIDENCE)	CLASS IIB (WEAK SUPPORTIVE EVIDENCE)	CLASS III (NOT INDICATED)
Acute conversion of PSVT	Vagal maneuver [C] Adenosine [C] Direct-current cardioversion [C]	Metoprolol,* propranolol* [C]	Verapamil [C]	
Prophylactic therapy	Digoxin [C] Metoprolol*	Propranolol* [B] Sotalol,* flecainide† [C]	Quinidine, propafenone,† verapamil [C] Procainamide [B] Catheter ablation [C]	Atenolol‡ [B] Amiodarone [C]

PSVT = paroxysmal supraventricular tachycardia.

*Beta-blocking agents should not be taken in the first trimester, if possible.

†Atrioventricular node–blocking agents in conjunction with flecainide and propafenone may be considered for certain tachycardias.

‡Atenolol is categorized in class C (drugs for use during pregnancy) by legal authorities in some European countries.

TABLE 78G-3 AHA/ASA Recommendations for Stroke Prevention During Pregnancy

CLASS	INDICATION	LEVEL OF EVIDENCE
Class IIb (weak supportive evidence)	For pregnant women with ischemic stroke or TIA and high-risk thromboembolic conditions, such as known coagulopathy or mechanical heart valves, the following options may be considered: adjusted-dose UFH throughout pregnancy, (e.g., a subcutaneous dose every 12 hours with activated partial thromboplastin time monitoring); adjusted-dose LMWH with factor Xa monitoring throughout pregnancy; or UFH or LMWH until week 13, followed by warfarin until the middle of the third trimester, when UFH or LMWH is then reinstituted until delivery.	C
	Pregnant women with lower risk conditions may be considered for treatment with UFH or LMWH in the first trimester, followed by low-dose aspirin for the remainder of the pregnancy.	C

LMWH = low-molecular-weight heparin; TIA = transient ischemic attack; UFH = unfractionated heparin.

TABLE 78G-4 ESH/ESC Guidelines for the Management of Hypertension During Pregnancy

- Nonpharmacologic treatment (including close supervision and restriction of activities) should be considered with SBP 140-149 mm Hg or DBP 90-95 mm Hg. In the presence of gestational hypertension (with or without proteinuria), drug treatment is indicated at blood pressure $\geq 140/90$ mm Hg. SBP levels ≥ 170 or DBP >110 mm Hg should be considered to represent an emergency necessitating hospitalization.
- In nonsevere hypertension, oral methyldopa, labetalol, calcium antagonists, and (less frequently) beta blockers are drugs of choice.
- In preeclampsia with pulmonary edema, nitroglycerin is the drug of choice. Diuretic therapy is inappropriate because plasma volume is reduced.
- As emergency treatment, IV labetalol, oral methyldopa, and oral nifedipine are indicated; IV hydralazine is no longer the drug of choice because of excess perinatal adverse effects. IV infusion of sodium nitroprusside is useful in hypertensive crises, but prolonged administration should be avoided.
- Calcium supplementation, fish oil, and low-dose aspirin are not recommended. However, low-dose aspirin may be used prophylactically in women with a history of early-onset preeclampsia.

DBP = diastolic blood pressure; ESH/ESC = European Society of Hypertension/European Society of Cardiology; IV = intravenous; SBP = systolic blood pressure.

TABLE 78G-5 ACC/AHA Recommendations for Anticoagulation Regimens in Pregnant Patients with Mechanical Prosthetic Valves

CLASS	INDICATION	LEVEL OF EVIDENCE
Class I (indicated)	Continuous therapeutic anticoagulation with frequent monitoring	B
	If warfarin is discontinued between weeks 6 and 12 of gestation, replace with continuous intravenous UFH, dose-adjusted UFH, or dose-adjusted subcutaneous LMWH.	C
	Up to 36 weeks of gestation, the therapeutic choice of continuous intravenous or dose-adjusted subcutaneous UFH, dose-adjusted LMWH, or warfarin should be discussed fully.	C
	If dose-adjusted LMWH is used, the LMWH should be administered twice daily subcutaneously to maintain the anti-Xa level between 0.7 and 1.2 units/mL 4 hours after administration.	C
	If dose-adjusted UFH is used, the aPTT should be at least twice control levels.	C
	If warfarin is used, the INR goal should be 3.0 (range, 2.5 to 3.5).	C
	Warfarin should be discontinued starting 2 to 3 weeks before planned delivery and continuous intravenous UFH given instead.	C
Class IIa (strong supportive evidence)	It is reasonable to avoid warfarin between weeks 6 and 12 of gestation because of the high risk of fetal defects.	C
	It is reasonable to resume UFH 4 to 6 hours after delivery and begin oral warfarin in the absence of significant bleeding.	C
	It is reasonable to give low-dose aspirin (75 to 100 mg/day) in the second and third trimesters of pregnancy, in addition to anticoagulation with warfarin or heparin.	C
Class III (not indicated)	LMWH should not be administered unless anti-Xa levels are monitored 4 to 6 hours after administration.	C
	Dipyridamole should not be used instead of aspirin as an alternative antiplatelet agent because of its harmful effects on the fetus.	B

aPTT = activated partial thromboplastin time; INR = international normalized ratio; LMWH = low-molecular-weight heparin; UFH = unfractionated heparin.

of data regarding their comparative efficacy. The European Society of Cardiology guidelines recognize the more favorable maternal outcome with oral anticoagulants and recommend that these agents be continued in the second and third trimesters until the 36th week (class IC). The guidelines also suggest that continuation of oral anticoagulants is reasonable in the first trimester if the warfarin dose is less than 5 mg/day.⁴

These strategies are complicated by the fact that low-molecular-weight heparin is not approved by the U.S. Food and Drug

Administration (FDA) for use in any patient with a mechanical prosthetic heart valve, and the FDA has issued an advisory warning against the use of enoxaparin (Lovenox) in pregnant women with mechanical prosthetic heart valves. The ACC/AHA guidelines for adult congenital heart disease emphasize that whichever anticoagulant strategy is chosen, women with mechanical prosthetic heart valves should be cared for at tertiary care centers where a multidisciplinary team with expertise and training in the management of such patients is responsible for their care.⁷

INTRODUCTION AND HISTORICAL PERSPECTIVE

Cardiovascular (CV) specialists require an understanding of exercise physiology, the benefits and risks associated with exercise, and the CV adaptations that occur with exercise training because of the following:

1. Many of the symptoms of CV disease appear during the stress of physical exertion.
2. Patients with or without CV disease request advice on exercise from CV specialists.
3. CV specialists are often consulted to decide whether "abnormal" findings in athletes represent disease or a physiologic response to exercise training.
4. CV specialists must commonly evaluate symptoms in active individuals.

Concern about the CV risks and benefits related to exercise is not new. In 1867, the London surgeon F.C. Sky equated the Oxford-Cambridge crew race to cruelty to animals and opined that such extreme exertion would cause heart disease.¹ Concern about rowers', runners', and bicyclists' hearts emerged in the late 19th century, when these activities migrated from being occupational competitions among only the working classes to being sporting activities for the social elite.¹ The normal CV adaptations to exercise training include resting bradycardia, global cardiac enlargement, and functional pulmonary and aortic valve flow murmurs. Evaluation of these normal adaptations by auscultation and cardiac percussion, the diagnostic tests of the day, led to their interpretation as signs of pathologic heart block, dilated cardiomyopathy, and valvular obstruction, respectively.¹ Concerns about the risks associated with prolonged and vigorous exercise were commonplace in the 19th and early 20th centuries. Clarence DeMar, the winner of seven Boston Marathons, took a 5-year hiatus from competition during the peak of his competitive years, in part because according to DeMar, "The frequent warnings of the doctors and fans of the danger to one's heart ... had left their impression."¹ Such concerns pertain to the present inasmuch as questions persist about the risks related to exercise and the effects of prolonged exercise on myocardial function.²

DEFINITION OF TERMS

"Physical activity" refers literally to any body movement, but in epidemiologic studies examining physical activity and health, it refers to activities producing substantial increases in oxygen (O_2) consumption. Physical activity can be performed during work or during leisure

and recreational tasks, and both work and leisure activities have been used to study the effects of physical activity on CV health. Physical activity designed to improve health or obtain performance benefits is considered "exercise." Exercise requiring primarily an increase in O_2 transport is referred to as "aerobic exercise," whereas exercise primarily stressing the skeletal muscular system is referred to as "resistance exercise." Repetitive exercise designed to increase the capacity of O_2 transport and the CV system is labeled "aerobic exercise training," whereas repetitive exercise designed to increase muscle strength is considered "strength" or "resistance" exercise training. Athletic and work activities can be divided into primarily aerobic or resistance exercise activities depending on their aerobic and strength components, but such divisions are arbitrary because aerobic activities such as jogging enhance leg muscular strength and resistance exercises such as weightlifting can stress the O_2 delivery system, depending on the resistance used and the number of exercise repetitions performed.

THE CARDIOVASCULAR RESPONSE TO EXERCISE AND EXERCISE TRAINING

The basic principles of the acute response to exercise and the CV adaptations to exercise training have been summarized elsewhere^{3,4} and are discussed in [Chapter 47](#); only principles critical to this chapter are repeated here. Physical activity acutely increases O_2 demand, which prompts the CV system to increase cardiac output (Q) and the arterial-venous (A-V) O_2 difference. The increase in Q is coupled to the energy required such that a 1-liter increase in oxygen consumption ($\dot{V}O_2$) produces a 5- to 6-liter increase in Q . Q is increased by augmentation of both the heart rate (HR) and stroke volume (SV). Several mechanisms increase the A-V O_2 difference, including shunting of blood from the renal and splanchnic beds to exercising muscle, hemoconcentration from loss of plasma fluid into the extravascular space as a result of the osmotic force produced by metabolites released into the interstitial space during exertion, and increased arterial oxygen extraction by active skeletal and cardiac muscle. Myocardial O_2 (MO_2) demand depends in part on HR and systolic blood pressure (SBP) and increases with exertion because both HR and SBP increase. As discussed in [Chapter 47](#), this increase in O_2 can produce ischemia in individuals with flow-limiting coronary artery lesions. In addition, the coronary arteries should dilate in response to the myocardial metabolic demands of exertion, but inadequate vasodilation or frank vasoconstriction develops with exercise in some individuals with coronary atherosclerosis because

of endothelial dysfunction.⁵ Cardiac ischemia, induced by exercise, can contribute to cardiac events during exercise, as discussed later.

The CV response to exercise has both an external and internal work rate.³ The external work rate is the $\dot{V}O_2$ required by the exercise task and, as mentioned earlier, is a direct determinant of Q . $\dot{V}O_2$ can also be estimated from treadmill speed and grade or from a stationary bicycle watt requirement. The internal work rate refers to the MO_2 required for the exercise task and is related directly to increases in HR. In contrast to Q , the HR response to exercise and therefore to MO_2 is not determined by the external work rate or $\dot{V}O_2$ but instead by the $\dot{V}O_2$ required relative to the individual's maximal exercise capacity—or $\dot{V}O_{2max}$. Individuals with higher exercise capacity and a greater $\dot{V}O_{2max}$ have a larger SV at any given external work rate such that any exercise task, as well as $\dot{V}O_2$ demand, requires a slower HR to generate the same, externally determined Q .

The primary CV effect of repetitive aerobic exercise sessions or aerobic exercise training is to increase maximal exercise capacity, measured physiologically by an increase in $\dot{V}O_{2max}$. This increase in healthy subjects results from increases in maximal Q and the maximal A-V O_2 difference.³ Because maximal HR is largely immutable, determined by age, and minimally affected by exercise training, the increase in maximal Q results from an increase in maximal SV. The increase in SV means that performing the same exercise task, which requires the same $\dot{V}O_2$, can be performed at a slower HR and a lower MO_2 or internal work rate. The reduction in HR and thereby MO_2 contributes to the increase in exercise capacity in patients with angina pectoris after exercise training (see Chapter 47). In addition to the increase in maximal exercise capacity, exercise training also increases endurance capacity, or the ability to perform submaximal effort for a prolonged period. This effect is a critically important component of the exercise training response because few work and recreational tasks require maximal CV effort.

Intense and prolonged aerobic exercise training produces an array of CV adaptations, commonly referred to as “athlete’s heart.” Such changes include an increase in resting SV and a decrease in resting HR. The physiologic mediators of these CV adaptations are not fully defined but are accompanied by and may be produced by increased resting vagal tone and reduced resting sympathetic tone. These changes in autonomic tone, most manifested in highly trained endurance athletes, can be associated with resting bradycardia, marked sinus arrhythmia, first-degree heart block, Mobitz I second-degree atrioventricular (AV) block, and even third-degree AV block during sleep. The reduced AV conduction velocity may make accessory conduction pathways, such as those of Wolff-Parkinson-White syndrome, more apparent. The increased vagal tone may also contribute to an increased prevalence of an early repolarization ST-segment pattern and ST-T wave abnormalities in athletes (Fig. 79-1).⁶ Four-chamber cardiac enlargement accompanies the increase in SV, but left ventricular (LV) wall thickness usually increases only mildly.⁴ Small increases in aortic root dimensions also occur, but increases in aortic size greater than expected for body size are not associated with athlete’s heart.⁷ In contrast to the extensive cardiac changes reported in endurance-trained athletes, strength exercise training produces modest increases in LV wall thickness with little change in chamber dimensions.⁴ Exercise training evokes numerous structural and functional cardiac adaptations (Fig. 79-2).⁸

Athletes have an increase in the average dimensions of all four cardiac chambers, but the dimensions generally do not exceed the upper limits of normal (ULN), and contractile function is usually preserved. For example, among 947 national-caliber and international-caliber Italian athletes, only 16 had LV wall thickness greater than 12 mm, the ULN.⁹ LV end-diastolic chamber size was also greater than 55 mm, the ULN value, in 45% of 1300 elite Italian athletes.¹⁰ The most marked increases in LV size occurred in the largest athletes, and LV dimensions were inversely related to HR ($r = -0.37$) and directly related to body surface area ($r = 0.76$).¹⁰

Cessation of exercise training, or “detraining,” may help in clinically differentiating adaptations to exercise training as a result of hypertrophic cardiomyopathy. Several studies have examined the effect of cessation of exercise training, or “detraining,” in endurance

FIGURE 79-1 Twelve-lead ECGs from asymptomatic athletes without structural or electrical diseases of the heart demonstrating common findings associated with exercise training. **A**, This trace shows sinus bradycardia and an incomplete right bundle branch block as a result of physiologic right ventricular dilation in a 23-year-old male professional hockey player. **B**, This trace shows sinus bradycardia with respirophasic sinus arrhythmia, precordial ST-segment elevation characteristic of benign normal early repolarization, and prominent precordial lead QRS voltage, often associated with underlying physiologic LVH, in a 19-year-old male distance runner.

athletes with eccentric LV hypertrophy (LVH), a geometric pattern of hypertrophy characterized by concomitant LV wall thickening and chamber dilation. Regression of eccentric LVH can occur in highly trained athletes after 6 to 34 weeks (mean, 13 weeks) of abstinence from exercise.¹¹ A detraining study of 40 Italian male athletes with eccentric LVH and peak fitness LV dimensions (mean \pm SD) of 61.2 ± 2.9 mm and LV wall thickness of 12.0 ± 1.3 mm reported complete normalization of wall thickness and a significant but incomplete reduction in cavity dilation after 5.8 ± 3.6 years of detraining (Figs. 79-3 and 79-4).¹² Because the LV wall thickening and concentric LVH common in strength-trained athletes can regress partially after 3 months and completely after 6 months of detraining, the later 6-month period is recommended for such diagnostic trials.¹³

THE EFFECTS OF HABITUAL PHYSICAL ACTIVITY ON CARDIOVASCULAR RISK (See also Chapter 42)

Multiple epidemiologic, cross-sectional studies comparing CV risk in healthy subjects at various levels of work and leisure physical activity have demonstrated that more active subjects have lower CV risk than do their more sedentary counterparts. The reduction in risk in the most active versus the least active subjects is approximately 30%.¹⁴ Similarly and as discussed in Chapter 47, patients participating in cardiac rehabilitation programs have a reduced risk for recurrent cardiac events.

The specific mechanisms mediating this effect have not been defined, but habitual physical activity has multiple potentially beneficial effects on atherosclerotic risk factors. Specifically, habitual physical activity reduces SBP, body weight, blood glucose, and triglycerides and increases high-density lipoprotein cholesterol.¹⁵ Some of the effects of exercise on blood pressure, glucose, and triglycerides

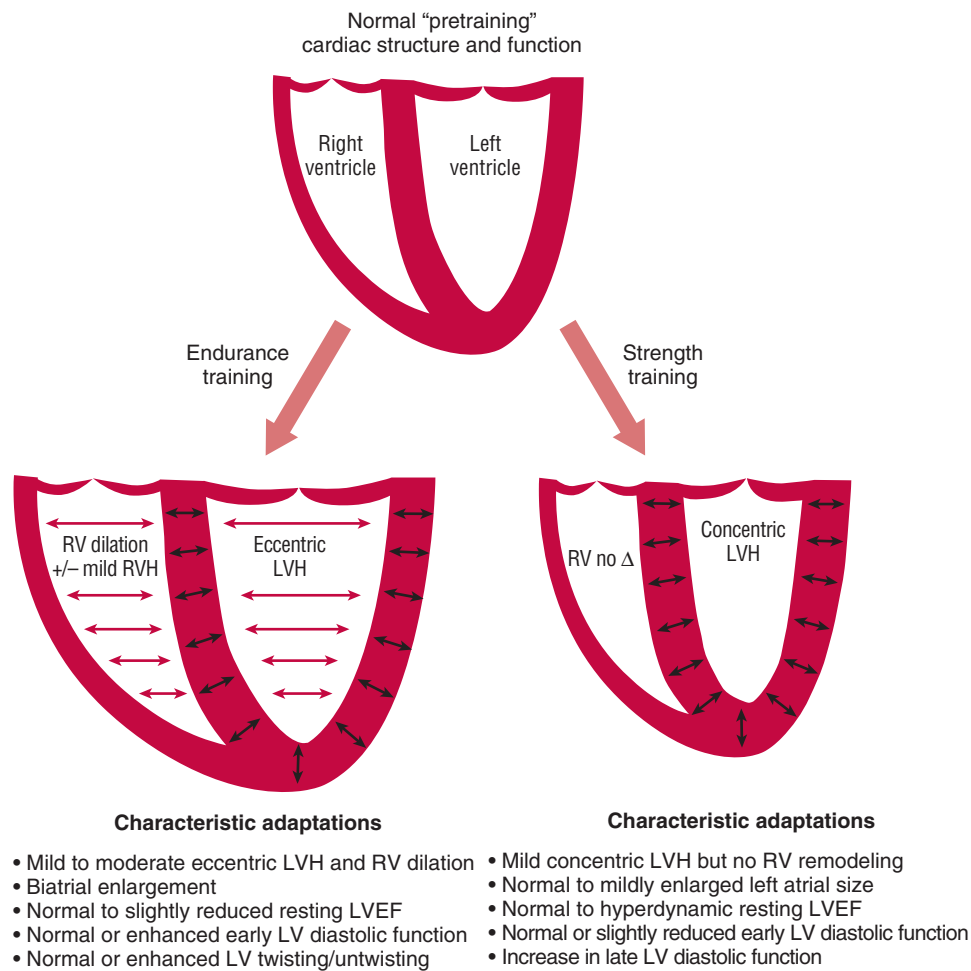

FIGURE 79-2 A summary of the ventricular remodeling that occurs with endurance and resistance exercise training. LVEF = LV ejection fraction; RV = right ventricle; RVH = RV hypertrophy. (From Weiner RB, Baggish AL: Exercise-induced cardiac remodeling. *Prog Cardiovasc Dis* 54:380, 2012.)

FIGURE 79-3 Echocardiographic measurements of LV chamber dimensions and LV wall thickness (LVWT) in 40 male Italian athletes measured at their peak of athletic performance (24 ± 4 years of age) and after detraining of 1 to 13 years (mean \pm SD = 5.6 ± 3.8 years). All had either increased LV chamber enlargement (LVE) of 60 mm or greater or LVWT of 13 mm or greater, at their peak. Nine of the athletes (22%) had persistent LVE greater than 60 mm, but LVWT normalized in all subjects. (From Pelliccia A, Maron BJ, Di Paolo FM, et al: Prevalence and clinical significance of left atrial remodeling in competitive athletes. *J Am Coll Cardiol* 46:690, 2005.)

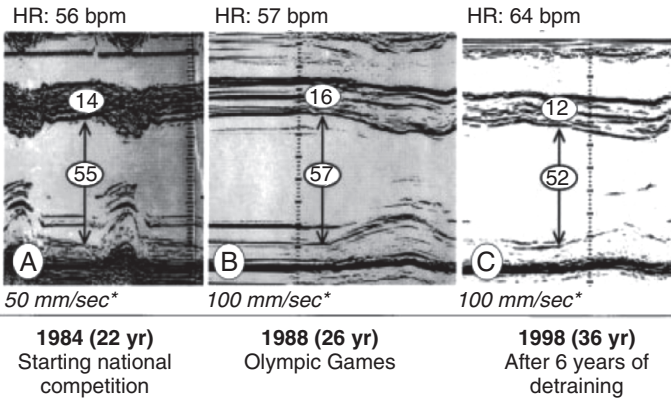

FIGURE 79-4 Serial echocardiograms from an elite canoeist at 22 years of age, when he joined the Italian national team; at 26 years of age, when he competed in the Olympics; and at 36 years of age, after 6 years of detraining. *Paper speed. Measurements in millimeters are in the ovals. bpm = beats/min. (From Pelliccia A, Maron BJ, Di Paolo FM, et al: Prevalence and clinical significance of left atrial remodeling in competitive athletes. *J Am Coll Cardiol* 46:690, 2005.)

occur acutely within 24 hours of a single aerobic exercise session.¹⁶ Such observations raise the possibility that the effects of “exercise training” on these parameters include an acute exercise effect magnified by the greater amount of exercise that can be performed by a trained person in a single exercise session because of the increase in exercise capacity produced by exercise training. Exercise training also produces potentially beneficial effects on clotting factors and inflammation. The increases in vagal tone may reduce the risk for ventricular fibrillation in response to ischemia.¹⁷

Cross-sectional studies, however, cannot prove that the reductions in CV risk are due to physical activity alone. Individuals who choose to be more physically active may inherit greater exercise capacity, thereby leading them to select active lifestyles and to have innately lower CV risk. Supporting this possibility is the observation that rats selected and bred over multiple generations for superior exercise performance have lower CV risk factors even though these risk factors were not used in the selection process.¹⁸ The same physiologic factors associated with increased exercise capacity may also be associated with reduced CV risk, and individuals choosing an active lifestyle may have lower CV risk independent of their exercise habits. This possibility appears unlikely, however, given the plethora of epidemiologic and experimental evidence linking increased physical activity with lower CV risk, but it remains a possibility that requires consideration.

THE CARDIOVASCULAR RISKS OF EXERCISE

Despite the putative benefits of habitual physical activity, convincing evidence has shown that vigorous physical activity, generally defined as six or more METS, or metabolic equivalents, of resting energy expenditure (3.5 mL of O₂ per kilogram of body weight per minute), transiently increases the risk for sudden cardiac death (SCD) and acute myocardial infarction (AMI).¹⁷ Most of this evidence is derived from studies comparing the hourly cardiac event rate during vigorous exertion with the rate during more sedentary activities. The pathologic substrate associated with these acute cardiac events varies by age, primarily because the prevalence of the pathologic cardiac conditions responsible for sudden death also varies by age. The predominant causes of exercise-related SCD in young individuals, usually defined as younger than 30 or younger than 40 years of age, are inherited and congenital conditions, including hypertrophic cardiomyopathy (see also Chapters 39 and 66) and anomalous origin of the coronary arteries¹⁹ (Table 79-1)—although acquired conditions such as myocarditis and cardiomyopathy can also cause

exercise-related SCD in young individuals.¹⁹ The causes of exercise-related SCD in the young may vary by geographic region. The primary cause of exercise-related SCD in Italy, for example, is arrhythmogenic right ventricular cardiomyopathy and not hypertrophic cardiomyopathy, the predominant cause in the United States.²³ Whether this difference results from differences in disease prevalence in the general population, from screening programs for athletes in Italy, or from other factors is unclear. The predominant cause of exercise-related AMI and SCD in adults is atherosclerotic cardiovascular disease (ASCVD).¹⁷ AMI and SCD in previously asymptomatic adults during exercise are usually,¹⁷ but not always²⁴ associated with acute coronary plaque disruption. Several triggering mechanisms for plaque disruption have been proposed, but increased flexing and bending of atherosclerotic coronary arteries may contribute.¹⁷ Such increased coronary flexing would be produced by the increase in HR and increased excursion of the coronary arteries because of increased end-diastolic and reduced end-systolic ventricular diameters with exercise. Adults with known ASCVD may also experience ventricular

fibrillation from exercise-induced ischemia as a result of the increased MO_2 produced by increases in HR and SBP.²⁴

The frequency of exercise-related CV events appears to be low, but several factors prevent calculation of a definitive incidence in either children or adults.¹⁷ Because of the rarity of exercise-related events, the studies available often include only a small number of subjects, so slight changes in the number of cases can greatly affect the incidence. A large population registry could address the paucity of events, but few such registries are available. The lack of systematically collected registries has forced many studies to depend on media reports of CV events, an approach that cannot guarantee total case ascertainment. Furthermore, even if all cases are collected, estimation of the denominator—or the population at risk for an exercise event—is difficult because the number of individuals engaged in vigorous exercise in the study cohort is often unknown. These caveats must be considered when evaluating current estimates, which have ranged from a low of one death per year for every 133,000 male high-school athletes and 769,000 female high-school athletes²⁰ to a high of one death per year for every 3100 male National Collegiate Athletic Association (NCAA) basketball players.²⁵ Estimates for adults suggest that one exercise-related death occurs per year for every 15,000 to 18,000 previously healthy adult men.¹⁷ These estimates are derived largely from studies from the early 1980s and are probably lower today because ASCVD events have decreased in American adults. The risk for exercise-related AMI may be sevenfold higher than that for SCD, so the risk for exercise-related AMI in the exercising population may be as high as 1 per 2000 men per year.¹⁷ All studies suggest that women have a much lower risk for exercise-related events.

THE APPROACH TO COMMON CLINICAL PROBLEMS IN SPORTS CARDIOLOGY

Athletes and active individuals may seek CV evaluation for a multitude of reasons, but the following section discusses several common clinical complaints in athletic patients and the clinical approach to their management.

Decreased Exercise Capacity

Athletes with decreased exercise capacity are frequently referred to CV specialists for evaluation. SV is a critical contributor to Q and therefore to exercise capacity, but $\dot{V}\text{O}_{2\text{max}}$ also requires maximal performance from its other CV components (HR and the A-V O_2 difference), as well as from the central nervous system, lungs, and skeletal muscle. Decrements in any of these components can adversely affect exercise performance. An inappropriately fast HR at low levels of exertion as a result of hyperthyroidism can decrease exercise performance, as can exercise-induced asthma, diseases of skeletal muscle, and reduced O_2 carrying capacity from anemia (often resulting from iron deficiency in female endurance athletes who eat a vegetarian diet). Atrial fibrillation or frequent premature beats during exercise can reduce exercise capacity. Other conditions not directly related to the CV system, including viral illnesses such as mononucleosis and hepatitis, can initially be manifested in athletes as decreased exercise capacity or exercise intolerance. These same issues can reduce exercise performance in older athletes, but occult coronary disease with atypical symptoms always requires consideration first in older patients. Our clinical experience suggests that many adult athletes with reduced exercise capacity referred for evaluation have LV diastolic dysfunction because the more obvious diagnoses are not referred. The clinical story is often that of a life-long endurance athlete with “borderline hypertension” who somehow avoided antihypertensive treatment either because of relatively low, albeit hypertensive pressure or because of patient preference. These patients frequently have mild resting hypertension but exhibit an exaggerated blood pressure response to exercise testing. Psychological factors and overtraining are additional causes of decreased exercise capacity in athletes. Psychological issues are generally seen in

young athletes who have lost their desire to compete before their parents have lost interest in the child's sport. This diagnosis often becomes clear if parents or other key adults are included in the patient's assessment. Some athletes appear to find it easier to use a medical excuse for stopping sports participation than to admit that they have lost interest, want to do other things in life, or “just aren't good enough” to continue.

Evaluation of athletes complaining of decreased exercise performance requires listening to the athlete's history carefully. Many complaints are dismissed in athletes because their exercise performance remains superior to that of nonathletes, but important cardiac conditions may develop in athletes sooner because of the physical demands of their sport. Evaluating performance times and training diaries in endurance athletes often helps plot the time course of the complaint. The conditions mentioned earlier must be excluded, as must obvious cardiac disease. Exercise testing using protocols designed to mimic the athlete's sport frequently helps document the complaint and its cause. Exercise echocardiography and/or cardiopulmonary exercise testing with specific attention to the oxygen pulse curve are useful when the history suggests diastolic dysfunction. The oxygen pulse can be calculated by dividing $\dot{V}\text{O}_2$ by HR, and assuming no important change in the A-V O_2 difference, it reflects SV. It can help determine when cardiac performance becomes a limiting factor during exercise. Long-term electrocardiographic monitoring, occasionally performed with implanted monitoring devices, can detect cardiac rhythm disorders in athletes with infrequent symptoms. Psychological and emotional issues should be diagnosed only after the exclusion of other more medical conditions and should be based on frank discussions with the athlete and family. Depression is a common cause of otherwise unexplained fatigue.

Overtraining is a complex interaction of psychological and physiologic fatigue in athletes that can occur after prolonged high-intensity training. Diminished exercise tolerance (sometimes with an elevated resting HR), the sensation of nocturnal fevers, and insomnia all characterize overtraining. The insomnia appears to be paradoxical because the athletes are often extremely fatigued but find it difficult to sleep as a result of restlessness and sometimes because of involuntary muscle contractions. Overtraining should be diagnosed only when other conditions are excluded and frequently requires a therapeutic trial of markedly reduced training to see whether the symptoms resolve and performance improves.

Abnormalities Found on Screening

Many athletes are referred to cardiologists because of CV abnormalities found on preparticipation screening. Both the American Heart Association (AHA)²⁶ and the European Society of Cardiology (ESC)²⁷ recommend preparticipation screening for athletes; the ESC, but not the AHA, recommends an electrocardiogram (ECG) in the screening evaluation. The debates on CV screening in general, on screening athletes versus screening all children, and on the role of the ECG exceed the scope of this chapter.²⁸ One widely cited Italian study suggests that screening markedly reduces cardiac events in athletes,²⁹ but studies from Minnesota³⁰ and Israel³¹ suggest that screening has no benefit. A National Institutes of Health consensus conference concluded that the data were insufficient to recommend routine screening of the general population or athletes with an ECG.³² Regardless of the scientific merit, many young athletes do undergo screening with an ECG, and abnormalities are detected.

Screening athletes with or without an ECG can detect a multitude of CV “problems.” Well-trained endurance athletes have a slow HR and large SV, which can produce normal pulmonic flow murmurs in young athletes, especially if the athlete is examined in the supine position when central blood volume is expanded. Such murmurs typically disappear when the athlete is sitting. Older athletes with hemodynamically insignificant aortic sclerosis may have aortic flow murmurs. Athletes can also have evidence on the ECG of biatrial hypertrophy, LVH, incomplete right bundle branch block, ST-T wave abnormalities, and conduction abnormalities.³³ Most of these abnormalities occur in endurance athletes undergoing intense

training. Such changes in strength-trained athletes or in endurance athletes with low training volumes should raise suspicion of a cardiac problem.

Most CV abnormalities found on screening are variants of normal, and most can be dismissed by a simple clinical examination and review of the ECG, with cardiac imaging procedures being used to remove any residual doubt. Some families and athletes have ongoing concern once a screening abnormality is identified, so having the athlete and family return in 3 to 6 months is sometimes useful, even when no abnormalities are found, to provide additional reassurance.

A common problem in athletes with a screening abnormality is “diagnostic creep”—the finding of a minor abnormality on screening such as early ECG repolarization, which prompts a second diagnostic test such as echocardiography, which reveals another borderline finding such as mild LVH, which may prompt another diagnostic test such as cardiac magnetic resonance imaging (MRI). Sometimes, because of the CV adaptations that accompany exercise training, each diagnostic study reveals an additional borderline abnormality, thus making it difficult for a clinician to declare the athlete “normal.” Screening abnormalities, especially if borderline abnormal, should be judged with less concern than definite abnormalities found in symptomatic athletes because the screening abnormalities will most frequently represent normal variants.

Cardiovascular Complaints in Athletes

Athletes are sensitive to changes in their physical being and exercise performance and are more likely to note early CV abnormalities because of the CV demands of exercise training and competition. On the other hand, some athletes, excessively concerned about anything that may affect their performance, seek evaluation for normal body sensations, such as muscular aches produced by new training regimens. Nevertheless, possible CV complaints in athletes should cause greater concern than borderline abnormalities found on screening, and such complaints require careful evaluation with techniques appropriate for the differential diagnosis.

Chest pain is a common complaint in young and old athletes, possibly because the importance of chest pain is emphasized in the general population and because athletes are increasingly concerned about the possible risks associated with exercise. Chest discomfort in athletes should never be dismissed summarily. Exertional chest pain may be the first sign of important cardiac diseases, including hypertrophic cardiomyopathy, anomalous coronary artery origin, or coronary artery atherosclerosis, but several issues are especially pertinent to athletes. Determining the duration of chest pain is important inasmuch as many athletes experience momentary chest pain. The sensation of momentary chest pain may accompany premature atrial or ventricular beats, possibly because contraction against closed AV valves produces a momentary sensation of chest fullness. Momentary chest pain with movement may also be related in athletes to muscle and joint issues. The relationship of chest pain to recent resistance exercise involving the chest muscles, such as push-ups and bench presses, is also important because such training is a frequent cause of chest discomfort in athletes. Some athletes who have died with anomalous coronary arteries had normal exercise stress test results,³⁴ thus indicating the importance of pursuing workups in athletes if the symptoms are worrisome, even when the initial testing results are normal. Such an approach differs distinctly from what we advise in asymptomatic athletes with borderline test results.

Vasovagal syncope, also known as neurally mediated syncope, is common in well-trained athletes—probably because of their resting bradycardia and large venous capacity, which permits sequestration of large amounts of blood when the athlete is upright and motionless.³⁵ Tilt-table testing is also often positive in athletes as a result of the same physiologic changes.³⁵ Neurally mediated syncope most often occurs in athletes immediately following exercise, particularly with abrupt termination of exercise. This common entity, known as “postexertional syncope,” is benign and can frequently be managed

by teaching the athlete avoidance techniques. The most important avoidance technique is for the athlete to keep moving after effort so that the muscle pump in the lower part of the legs continues to return blood to the systemic circulation. The key issue in evaluating syncope in athletes is whether the syncope occurred during exertion. Syncope at rest or immediately after exercise under conditions consistent with vasovagal syncope or postural syncope is usually due to these conditions. In contrast, syncope during exercise should prompt a careful search for more serious problems, including hypertrophic cardiomyopathy, aortic stenosis (AS), cardiac arrhythmia, or anomalous coronary arteries.³⁵

DETERMINING ATHLETIC ELIGIBILITY

The 36th Bethesda Conference provided guidelines for determining eligibility for competition in athletes.³⁶ Guidelines are necessarily restrictive because they are used by a wide variety of clinicians, many of whom will have no special qualifications or expertise in evaluating athletes. Nevertheless, as clinicians gain more experience in evaluating athletes with minor variants of CV disease, many of these guidelines will probably ultimately be viewed as overly restrictive. For example, the recommendation for athletic restriction in athletes with long-QT syndrome³⁷ and for athletes with defibrillators³⁸ has been challenged as excessively limiting. At the present time, however, these guidelines represent the best available consensus opinion on how to advise athletes regarding their risk related to competition.

We use these guidelines as the basis for most of our recommendations but alter the final decision depending on multiple factors—including our perception of the athlete’s risk given the severity of the lesion and symptoms, the importance of participation for the athlete’s mental health, the danger to others, and the athlete’s and family’s willingness to share risk in making the decision. The diagnosis, its attendant risk, and the basis for any recommendations also require discussion, if the athlete agrees, with other key individuals such as parents, school or team administrators, coaches, athletic trainers, and business agents. We use a similar decision-making approach with older athletes, although they usually have a greater ability to understand and assume personal risk.

ADVISING ADULT ATHLETES WITH ATHEROSCLEROTIC CARDIOVASCULAR DISEASE

Vigorous exercise increases the risk for SCD and AMI in adults with occult ASCVD, and the increased risk with exercise is probably even greater in individuals with diagnosed disease.³⁹ Nevertheless, many adults with ASCVD want to return to active athletic competition, often in demanding endurance events such as marathon running or long-distance cycling. Imaging techniques such as scanning for coronary artery calcification have expanded the detection of asymptomatic and presymptomatic disease. All athletes with ASCVD require an explanation that vigorous exercise acutely increases their CV risk and that lesser amounts of exercise probably confer as much medical benefit. Despite such discussion, many such athletes want to return to competition or intense exercise training. Plaque stability may increase with decreasing lipid content of the plaque⁴⁰; evidence also shows that most plaque regression occurs within 2 years of aggressive lipid lowering.⁴¹ Consequently, in athletes strongly wishing to return to competition, we advise 2 years of aggressive lipid treatment with the goal of achieving the lowest possible serum lipid levels before returning to competition. We also emphasize the importance of blood pressure control and tobacco avoidance, as well as the need to report symptoms that may indicate progression of disease. This approach allows the athlete to have the hope of further competition, but it also helps motivate them to adhere to risk reduction strategies.

Adult athletes receiving lipid-lowering or antihypertensive treatment occasionally inquire whether their medications should be stopped before endurance athletic competition. We encourage athletes to continue aspirin and other antiplatelet medications under the assumption that they may help avoid an acute cardiac event if plaque disruption occurs. We continue therapy with a beta-adrenergic-blocking agent to avoid the increase in adrenergic activity that occurs when use of these drugs is stopped abruptly. We generally discontinue antihypertensive medications on the day of the athletic event because exercise acutely reduces blood pressure and we want to avoid making the athlete more hypotensive after exertion. We discontinue statins for 5 to 7 days before endurance athletic competition. Statins magnify the increase in creatine kinase (CK) that occurs with exercise,⁴² and the combined effects of statins and exercise could lead to rhabdomyolysis.

VALVE DISEASE IN ATHLETES

Valvular disease in athletes should be managed according to principles for the nonathletic population, although several issues merit note.⁴³

Athletes with echocardiographic evidence of critical AS should undergo careful evaluation for symptoms and maximal exercise stress testing that simulates as closely as possible the athlete's typical exercise training and competition.⁴³ Many adult athletes with critical AS ignore important dyspnea at the start of exercise because it dissipates within 5 to 10 minutes, but this "warm-up dyspnea" frequently indicates clinically important AS.

Athletes generally tolerate aortic regurgitation (AR) well, probably because the increased HR during exercise decreases diastole and regurgitant flow.⁴³ Consequently, we rarely restrict athletic competition despite severe AR unless there is evidence of ventricular deterioration. We also rarely restrict resistance exercise in this group despite concern that this type of exercise increases regurgitation because no data to our knowledge indicate benefit of such restriction.

Great concern exists regarding exercise and aortic dissection in athletes with a bicuspid aortic valve (BAV), and some clinicians have restricted participation in this group because of concern that athletics will contribute to aortic dilation.⁴³ Given the prevalence of a BAV valve in approximately 1% of the population and the rarity of aortic dissection in young athletes, we do not restrict activity unless the aortic diameter is greater than 45 mm, but we evaluate athletes annually with an aortic size of 40 to 45 mm. Athletes found to have a BAV valve should undergo some form of imaging to determine proximal ascending aortic dimensions at the time of diagnosis and then should be monitored by serial imaging during their years of competitive sport participation. There is no standard time interval for repeated imaging of athletes with BAV valves, but some factors can aid in this decision, including aortic root size at diagnosis and family history of aortopathy.

ELEVATED "CARDIAC ENZYMES" IN ATHLETES

Cardiac troponin T and I (cTnT and cTnI) are used as markers of myocardial necrosis, but increases in cTnT occur in athletes following prolonged exertion, such as a marathon run,⁴⁴ and even after a brief intense treadmill run lasting only 30 minutes (Fig. 79-5).⁴⁵ These observations are reminiscent of increases in the myocardial isoform of CK (CK-MB) reported in endurance athletes in the 1980s.⁴⁶ Endurance athletes were subsequently documented to have increased concentrations of CK-MB and satellite cells in their leg muscles. This observation led to the theory that increased CK-MB levels after exercise resulted from the ability of satellite cells to make CK-MB. The CK-MB in satellite cells is released when the satellite cells themselves are damaged during exercise.⁴⁶ Increased concentrations of cardiac troponins have not been documented in the skeletal muscle of

FIGURE 79-5 cTnT values obtained 30 minutes after these 72 runners completed the 2002 or 2003 London Marathon (a 42-km footrace). The AMI level for this assay was set at greater than 0.05 $\mu\text{g/liter}$. Thirty-six percent of the runners exceeded this value. (From Shave RE, Whyte GP, George K, et al: Prolonged exercise should be considered alongside typical symptoms of acute myocardial infarction when evaluating increases in cardiac troponin T. *Heart* 91:1219, 2005.)

athletes to our knowledge, but increased cTnT blood levels have occurred in patients with skeletal muscle disease.⁴⁷ Regardless of the origin of the elevated cTn, clinicians need to be aware that endurance athletes may have elevated cTn levels after exertion and that the diagnosis of an acute cardiac event in an athlete requires confirmatory evidence in the form of either symptoms, the ECG, or echocardiographic evidence of myocardial injury.⁴⁴

POSSIBLE MYOCARDIAL FIBROSIS IN ATHLETES

On the other hand, these elevations in cTnT may not be totally benign. At least three studies have detected the presence of late gadolinium enhancement (LGE) with cardiac MRI in 12% to 50% of veteran endurance athletes.⁴⁸ Athletes with LGE had exercised for much of their lives and had cardiac dimensions larger than comparison athletes did. The LGE volume was small and often located near right ventricular insertion sites, thus suggesting mechanical stress as the cause. The presence of LGE raises the possibility that prolonged exercise training produces myocardial fibrosis, but this possibility requires more extensive study for confirmation and to determine its significance.

CONCLUSION

CV clinicians require a working knowledge of exercise physiology, the CV adaptations to exercise training, and the risks and benefits of exercise to advise and evaluate active patients appropriately. Clinicians should endeavor to avoid overreacting to borderline findings detected on CV screening of asymptomatic athletes, as well as avoid ignoring possible cardiac symptoms in active individuals. Sports cardiology is emerging as a subspecialty of cardiology, but general cardiologists can deal with many of the management issues and queries adequately if they understand the CV adaptations to exercise and the most common pathologic conditions that affect athletic patients.

Cardiovascular morbidity and mortality represent a special concern in patients with known (or with risk factors for) cardiovascular disease who undergo noncardiac surgery. The cost of perioperative myocardial injury adds substantially to the total health care expenditure, with an average increased length of stay (LOS) of 6.8 days for patients with perioperative myocardial ischemic injury. Perioperative cardiovascular complications not only affect the immediate period but may also influence outcome over subsequent years. The evidence base for managing patients with cardiovascular disease in the context of noncardiac surgery has grown in recent decades, beginning with identification of those at greatest risk and progressing to randomized trials to identify strategies for reducing perioperative cardiovascular complications. Guidelines provide information for the management of high-risk patients and disseminate best practices. Indeed, over the last decade, mortality rates for all major surgeries have dropped in parallel with implementation of these practices.¹ This chapter attempts to distill this information by incorporating guidelines available from the American College of Cardiology Foundation (ACCF)/American Heart Association (AHA) and from the European Society of Cardiology (ESC).^{2,3} The ACCF/AHA plan an update to this guideline to be published in September 2014.

(An update on this guideline is available online at ExpertConsult.)

Additionally, controversy exists regarding research conducted at Erasmus University by Don Poldermans (the DECREASE [Dutch Echocardiographic Cardiac Risk Evaluation Applying Stress Echocardiography] studies), in which an investigative committee found serious shortcomings in the procedure used to record patient consent, submission of publications based on unreliable data, and scientifically inaccurate data collection (http://www.erasmusmc.nl/5663/135857/3675250/3706798/Integrity_report_2012-10.pdf?lang=en. Accessed December 8, 2012). We included these studies for completeness, but their importance with regard to clinical decision making should take into account questions regarding data quality and that the guidelines committee has yet to incorporate this concern into new recommendations.

ASSESSMENT OF RISK

Much of the contemporary study of perioperative cardiac risk has focused on the development of clinical risk indices. The most widely

used index was developed in a study of 4315 patients 50 years or older undergoing elective major noncardiac procedures in a tertiary care teaching hospital. The index includes six independent predictors of complications in a revised cardiac risk index (RCRI): high-risk type of surgery, history of ischemic heart disease, history of congestive heart failure, history of cerebrovascular disease, preoperative treatment with insulin, and preoperative serum creatinine concentration greater than 2.0 mg/dL. Cardiac complication rates rise with an increasing number of these risk factors. Patients are stratified into low, intermediate, or high cardiovascular risk on the basis of having 0, 1 to 2, or 3 or more factors included in the RCRI, respectively. The RCRI has become the standard tool for assessing the probability of perioperative cardiac risk in a given individual and serves to direct the decision to perform cardiovascular testing and implement perioperative management protocols. The RCRI has undergone validation in vascular surgery populations and is used to predict long-term outcome and quality of life, although one group has advocated inclusion of age as a risk factor. Another risk index was developed from the American College of Surgeons 2007 National Surgical Quality Improvement Program data base.⁴ Of 211,410 patients, perioperative myocardial infarction (MI) or cardiac arrest developed in 1371 (0.65%). Multivariate logistic regression analysis identified five predictors of perioperative MI or cardiac arrest: type of surgery, dependent functional status, abnormal creatinine level, American Society of Anesthesiologists class, and increasing age.

Ischemic Heart Disease

Numerous points of entry lead to evaluation of patients before they undergo noncardiac surgery. Primary physicians or cardiologists may examine such patients. However, many patients are evaluated only immediately before surgery by the surgeon or anesthesiologist. The stress related to noncardiac surgery may raise the heart rate (HR) preoperatively, which is associated with a high incidence of symptomatic and asymptomatic myocardial ischemia. Preoperative clinical evaluation of patients may therefore identify stable or unstable coronary artery disease (CAD). Patients with acute manifestations of CAD such as unstable angina or decompensated heart failure of ischemic origin have a high risk for the development of further decompensation or myocardial necrosis and death during the perioperative period. Such patients clearly warrant further evaluation

and medical stabilization. If the noncardiac surgery is truly an emergency, several older case series have shown that intra-aortic balloon pump counterpulsation can provide short-term myocardial protection beyond that afforded by maximal medical therapy, although this measure is seldom used today.

If the patient does not have unstable symptoms, identification of known or symptomatic stable CAD or risk factors for CAD can guide further diagnostic evaluation or changes in perioperative management. In determining the extent of preoperative evaluation it is important to not perform testing unless the results will affect perioperative management. Such changes in management include cancellation of surgery if the risk-benefit ratio is prohibitive, delay of surgery for further medical management, coronary interventions before surgery, use of an intensive care unit (ICU), and changes in monitoring. As discussed later, current data challenge the benefit of preoperative coronary revascularization, findings that can limit the need for extensive testing.

Patients with stable angina represent a continuum from mild angina with extreme exertion to dyspnea with angina after walking up a few stairs. Patients who manifest angina only after strenuous exercise often do not have signs of left ventricular dysfunction and can generally be stabilized with adequate medical therapy—particularly treatment with aspirin, beta-adrenergic–blocking agents, and statins. In contrast, patients with dyspnea on mild exertion would be at high risk for the development of perioperative ventricular dysfunction, myocardial ischemia, and possibly MI. Such patients have a high probability of having extensive CAD and warrant consideration of additional monitoring or cardiovascular testing depending on the surgical procedure, institutional factors, and results of the previous evaluation.

Traditionally, assessment of the coronary risk associated with noncardiac surgery in patients with previous MI was based on the time interval between the MI and surgery. Multiple studies have demonstrated an increased incidence of reinfarction after noncardiac surgery if the previous MI had occurred within 6 months of the operation. Improvements in perioperative care have shortened this time interval, but these criteria have less relevance in the current era of thrombolytic agents, primary percutaneous revascularization, and routine coronary risk stratification after acute MI. Although some patients after a recent MI may continue to have myocardium at risk for subsequent ischemia and infarction, most patients in the United States will have had their critical coronary stenosis evaluated and revascularized when appropriate and should receive maximal medical therapy. The AHA/ACC Task Force on Perioperative Evaluation of the Cardiac Patient Undergoing Noncardiac Surgery has suggested that the highest-risk patients are those within 30 days of MI, during which time plaque and myocardial healing occur. After this period, risk stratification is based on the features of the disease (i.e., those with active ischemia are at highest risk). However, a study using administrative data from California demonstrated that the rate of perioperative cardiac morbidity and mortality remained elevated for at least 60 days after a myocardial infarction.^{4a}

Hypertension

In the 1970s a series of case studies changed the prevailing thought that the use of antihypertensive agents should be discontinued before surgery. The reports suggested that poorly controlled hypertension was associated with untoward hemodynamic responses and that antihypertensive agents should be continued perioperatively. However, several large prospective studies were unable to establish mild to moderate hypertension as an independent predictor of postoperative cardiac complications such as cardiac death, postoperative MI, heart failure, or arrhythmias. The approach to patients with hypertension therefore relies mostly on management strategies from the nonsurgical literature.

A hypertensive crisis in the postoperative period—defined as diastolic blood pressure (BP) higher than 120 mm Hg and clinical evidence of impending or actual end-organ damage—poses a definite risk for MI and cerebrovascular accidents. Diagnostic criteria include

papilledema or other evidence of increased intracranial pressure, myocardial ischemia, or acute renal failure. Precipitants of hypertensive crises include preeclampsia or eclampsia, pheochromocytoma, abrupt withdrawal from clonidine therapy before surgery, chronic use of monoamine oxidase inhibitors with or without sympathomimetic drugs, and inadvertent discontinuation of antihypertensive therapy.

Chronic hypertension may predispose patients to perioperative myocardial ischemia because these patients more commonly have concomitant CAD. Recent clinical trials have yielded mixed conclusions regarding the relevance of hypertension to perioperative outcomes. A retrospective evaluation of 2462 patients undergoing vascular surgery showed that adding hypertension to a risk prediction model improved its prognostic ability.⁵ In contrast, in the POISE (PeriOperative ISchemic Evaluation) trial of beta-adrenergic blockade, 62% of the 8351 subjects had chronic hypertension, but it was not a predictor of postoperative stroke or death.⁶ Thus the preoperative BP of hypertensive patients with known peripheral and coronary vascular disease should be monitored and controlled.

Whether patients with mild to moderate hypertension should be considered at greater risk for perioperative myocardial ischemia remains uncertain. Surgery generally need not be postponed or canceled in otherwise uncomplicated patients with mild to moderate hypertension. Antihypertensive medications should be continued perioperatively, and BP should be maintained near preoperative levels to reduce the risk for myocardial ischemia. In patients with more severe hypertension, such as a diastolic BP higher than 110 mm Hg, the potential benefits of delaying surgery to optimize antihypertensive medications should be weighed against the risk associated with delaying the surgical procedure. With rapidly acting intravenous agents, BP can usually be controlled within several hours. As cited in the ACCF/AHA guidelines (referred to hereafter as the guidelines), Weksler and colleagues studied 989 chronically hypertensive patients about to undergo surgery for noncardiac reasons with a diastolic BP between 110 and 130 mm Hg and no previous MI, unstable or severe angina pectoris, renal failure, pregnancy-induced hypertension, left ventricular hypertrophy, previous coronary revascularization, aortic stenosis, preoperative dysrhythmias, conduction defects, or stroke. The control group had their surgery postponed and remained in the hospital for control of BP, and the study patients received 10 mg of nifedipine delivered intranasally.² The study did not find statistically significant differences in postoperative complications, thus suggesting that this subset of patients without manifest cardiovascular comorbid conditions can proceed with surgery despite elevated BP on the day of surgery.

Heart Failure

Heart failure is associated with perioperative cardiac morbidity after noncardiac surgery in virtually all studies. Goldman and colleagues, as cited in the guidelines, identified a third heart sound or signs of heart failure as portending the highest perioperative risk. In patients with signs or symptoms of heart failure who are scheduled for noncardiac surgery, causes of the heart failure require characterization.² The preoperative evaluation should aim to identify the underlying coronary, myocardial, and/or valvular heart disease and assess the severity of the systolic and diastolic dysfunction. Hammill and associates used Medicare claims data to evaluate short-term outcomes in patients with heart failure, CAD, or neither who underwent major noncardiac surgery.⁷ Elderly patients with heart failure who undergo major surgical procedures were found to have substantially higher risk for operative mortality and hospital readmission than were other patients, including those with CAD, admitted for the same procedures. Use of codes from the International Classification of Diseases, ninth edition, for patient identification does not permit differentiation between heart failure with preserved or impaired left ventricular function, and thus the preoperative evaluation can influence preoperative management beyond just a high-risk classification; in particular, this assessment may influence perioperative fluid and vasopressor management.

Treatment of decompensated hypertrophic cardiomyopathy differs from that of dilated cardiomyopathy, and thus the preoperative

evaluation can influence perioperative management; in particular, this assessment may influence perioperative fluid and vasopressor management. Ischemic cardiomyopathy is of greatest concern because the patient has substantial risk for the development of further ischemia, which can lead to myocardial necrosis and potentially a downward spiral. A pulmonary artery catheter or intraoperative transesophageal echocardiography (TEE) may be helpful in such patients.

Obstructed hypertrophic cardiomyopathy was formerly regarded as a high-risk condition associated with high perioperative morbidity. A retrospective review of perioperative care in 35 patients, however, suggested that the risk related to general anesthesia and major noncardiac surgery is low in such patients. This study also suggested spinal anesthesia to be a relative contraindication in view of the sensitivity of cardiac output to preload in this condition. Haering and colleagues, as cited in the guidelines, studied 77 patients with asymmetric septal hypertrophy identified retrospectively from a large data base.² Forty percent of the patients had one or more adverse perioperative cardiac events, including one patient who had an MI and ventricular tachycardia that required emergency cardioversion. Most of the events consisted of perioperative congestive heart failure, and no perioperative deaths occurred. Unlike the finding in the original cohort of patients, the type of anesthesia was not an independent risk factor. Important independent risk factors for an adverse outcome (as seen generally) included major surgery and increasing duration of surgery.

VALVULAR HEART DISEASE (See also Chapter 63)

Aortic stenosis places patients at increased risk. Critical stenosis is associated with the highest risk for cardiac decompensation in patients undergoing elective noncardiac surgery. As cited in the guidelines, Kertai reported a substantially higher rate of perioperative complications in patients with severe aortic stenosis than in those with moderate aortic stenosis (31% [5/16] versus 11% [10/92]).^{2,8} The presence of any of the classic triad of angina, syncope, and heart failure in a patient with aortic stenosis should prompt further evaluation and potential interventions (usually valve replacement). Many patients with severe or critical aortic stenosis are asymptomatic. Preoperative patients with aortic systolic murmurs warrant a careful history and physical examination—and often further evaluation. Several recent case series of patients with critical aortic stenosis have demonstrated that when necessary, noncardiac surgery can be performed with acceptable risk. For the most part, these series have included patients with few or no symptoms but a valve area smaller than 0.5 cm². Aortic valvuloplasty is an alternative option for some patients. Although the long-term outcome of patients who undergo aortic balloon valvuloplasty is generally poor, primarily because of restenosis, this procedure can provide temporary benefit before noncardiac surgery in patients who cannot undergo valve replacement in the short term. The substantial risk for procedure-related morbidity and mortality requires careful consideration before recommending this strategy to lower the risk imposed by noncardiac surgery.

Mitral valve disease is associated with a lower risk for perioperative complications than aortic stenosis is, although occult mitral stenosis secondary to rheumatic heart disease sometimes occurs and can lead to severe left-sided heart failure in patients with tachycardia (e.g., uncontrolled atrial fibrillation) and/or volume loading. In contrast to aortic valvuloplasty, mitral valve balloon valvuloplasty often yields both short- and long-term benefit, especially in younger patients with predominantly mitral stenosis but without severe mitral valve leaflet thickening or significant subvalvular fibrosis and calcification.

In perioperative patients with a functioning prosthetic heart valve, antibiotic prophylaxis and anticoagulation are major issues. All patients with prosthetic valves who undergo procedures that can cause transient bacteremia should receive prophylaxis. In patients with prosthetic valves the risk for increased bleeding during a procedure while receiving antithrombotic therapy must be weighed against

the increased risk for thromboembolism caused by stopping the therapy. Common practice in patients undergoing noncardiac surgery with a mechanical prosthetic valve in place is cessation of oral anticoagulants 3 days before surgery. This allows the international normalized ratio to fall to less than 1.5 times normal; oral anticoagulants can then be resumed on postoperative day 1. An alternative approach in patients at high risk for thromboembolism is conversion to heparin during the perioperative period, which can then be discontinued 4 to 6 hours before surgery and resumed shortly thereafter. A multicenter, single-arm cohort study of 224 high-risk patients (prosthetic valves, atrial fibrillation, and a major risk factor) investigated the use of low-molecular-weight heparin (LMWH) as a preoperative bridge to warfarin anticoagulation in which warfarin was withheld for 5 days and LMWH was given 3 days preoperatively and at least 4 days postoperatively. The overall rate of thromboembolism was 3.6%, and the overall rate of cardioembolism was 0.9%. Major bleeding was seen in 6.7% of subjects, although only 8 of 15 episodes occurred during the administration of LMWH.⁹ LMWH is cost-effective because it helps reduce the duration of the hospital stay, but two studies have shown a residual anticoagulation effect in as many as two thirds of patients.^{10,11}

Many current prosthetic valves have a lower risk for valve thrombosis than the older ball-in-cage valves do, so the risk associated with heparin may outweigh its benefit in the perioperative setting. According to the AHA/ACCF guidelines, heparin can usually be reserved for high-risk patients. High risk is defined by the presence of a mechanical mitral or tricuspid valve or a mechanical aortic valve and by certain risk factors, including atrial fibrillation, previous thromboembolism, hypercoagulable condition, older-generation mechanical valves, an ejection fraction lower than 30%, or more than one mechanical valve.¹² Subcutaneous LMWH or unfractionated heparin offers an alternative outpatient approach but has received only a tentative recommendation. Discussion between the surgeon and cardiologist regarding optimal perioperative management is critical.

CONGENITAL HEART DISEASE IN ADULTS (See also Chapter 62)

Congenital heart disease afflicts 500,000 to 1 million adults in the United States. The nature of both the underlying anatomy and any anatomic correction affects the perioperative plan and incidence of complications, which include infection, bleeding, hypoxemia, hypotension, and paradoxical embolization. A major concern in patients with congenital heart disease is the presence of pulmonary hypertension and Eisenmenger syndrome. Regional anesthesia has traditionally been avoided in these patients because of the potential for sympathetic blockade and worsening of the right-to-left shunt. However, a review of the published literature incorporating 103 cases found that overall perioperative mortality was 14%; patients receiving regional anesthesia had a mortality of 5%, whereas those receiving general anesthesia had a mortality of 18%. The authors concluded that most deaths probably resulted from the surgical procedure and the disease rather than from anesthesia. Although perioperative and peripartum mortality was high, many anesthetic agents and techniques had been used with success. Patients with congenital heart disease are at risk for infective endocarditis and should receive antibiotic prophylaxis. A recent review has discussed the anesthetic management of these patients in detail.⁸

ARRHYTHMIAS (See Chapters 34 Through 39)

Cardiac arrhythmias commonly occur in the perioperative period, particularly in older adults or patients undergoing thoracic surgery. Predisposing factors include previous arrhythmias, underlying heart disease, hypertension, perioperative pain (e.g., hip fractures), severe anxiety, and other situations that heighten adrenergic tone. In a prospective study of 4181 patients 50 years or older, supraventricular arrhythmia occurred in 2% during surgery and in 6.1% after surgery.

Perioperative atrial fibrillation raises several concerns, including the incidence of stroke (see Chapter 38). Winkel and colleagues evaluated 317 patients without atrial fibrillation who were undergoing major vascular surgery to determine the incidence of new-onset atrial fibrillation and its association with adverse cardiovascular outcomes. They reported an incidence of 4.7% and more than a sixfold increase in cardiovascular death, MI, unstable angina, and stroke in the first 30 days and a fourfold increase over the next 12 months.¹³ Early treatment to restore sinus rhythm or control the ventricular response and initiate anticoagulation is therefore indicated. Prophylactic use of intravenous diltiazem in randomized, placebo-controlled trials of patients undergoing high-risk thoracic surgery was found to reduce the incidence of clinically significant atrial arrhythmias.² Balser and colleagues studied 64 cases of postoperative supraventricular tachyarrhythmia. After the administration of adenosine, patients who remained in supraventricular tachyarrhythmia were prospectively randomly assigned to receive either intravenous diltiazem or intravenous esmolol for control of the ventricular rate; intravenous esmolol produced a more rapid (2-hour) conversion to sinus rhythm than did intravenous diltiazem.¹⁴ Figure 80-1 presents an algorithm for the management of atrial fibrillation.

Although older studies identified ventricular arrhythmias as a risk factor for perioperative morbidity, recent studies have not confirmed this finding. O'Kelly, as cited in the guidelines, studied a consecutive sample of 230 male patients with known CAD or at high risk for CAD who underwent major noncardiac surgical procedures.² Preoperative arrhythmias were associated with intraoperative and postoperative arrhythmias, but nonfatal MI and cardiac death were not substantially more frequent in those with previous perioperative arrhythmias. Amar and coworkers studied 412 patients undergoing major thoracic surgery and determined that even though the incidence of nonsustained ventricular tachycardia was 15%, it was not associated with a poor outcome.¹⁵ Despite this finding, the presence of an arrhythmia in the preoperative setting should provoke a search for underlying cardiopulmonary disease, ongoing myocardial ischemia or infarction, drug toxicity, or electrolyte or metabolic derangements.

Conduction abnormalities can increase perioperative risk and may require placement of a temporary or permanent pacemaker. On the other hand, patients with intraventricular conduction delays, even in the presence of a left or right bundle branch block but without a history of advanced heart block or symptoms, rarely progress to complete

heart block perioperatively. The availability of transthoracic pacing units has decreased the need for temporary transvenous pacemakers.

THE DECISION TO UNDERGO DIAGNOSTIC TESTING

The ACCF/AHA and ESC both proposed algorithms based on the available evidence and incorporated the class of recommendations and level of evidence into each step (Fig. 80-2). Current algorithms use a stepwise bayesian strategy that relies on assessment of clinical markers, previous coronary evaluation and treatment, functional capacity, and surgery-specific risk (as outlined later). Successful use of the algorithms requires an appreciation of the different levels of risk attributable to certain clinical circumstances, levels of functional capacity, types of surgery, and how the information from any diagnostic testing will influence perioperative management.

Multiple studies have attempted to identify clinical risk markers for perioperative cardiovascular morbidity and mortality. As described earlier, patients with unstable coronary syndromes and severe valvular disease have active cardiac conditions. Patients with known stable CAD are at intermediate risk. Other clinical risk factors in the RCRI make up the remainder of the predictors of intermediate risk (history of congestive heart failure, history of cerebrovascular disease, preoperative treatment with insulin, and preoperative serum creatinine concentration >2.0 mg/dL). Cardiovascular disease also has clinical risk markers that have been classified as "low-risk factors," each of which is associated with variable levels of perioperative risk. Table 80-1 shows the classification of perioperative clinical risk markers for the purpose of assessing the need for further testing.

As described with regard to the anginal pattern, exercise tolerance is one of the strongest determinants of perioperative risk and the need for invasive monitoring. In one study of outpatients referred for evaluation before major noncardiac procedures, patients were asked to estimate the number of blocks that they could walk and flights of stairs that they could climb without experiencing cardiac symptoms. Patients who could not walk four blocks and could not climb two flights of stairs were considered to have poor exercise tolerance and had twice as many perioperative cardiovascular complications as did those with better functional status. The likelihood of a serious complication related inversely to the number of blocks that could be

walked or flights of stairs that could be climbed. Several scales based on activities of daily living have been proposed to assess exercise tolerance. The current guidelines advocate one such scale (the Duke Activity Scale Index) (Table 80-2). (See also Chapters 47 and 79.)

The type of surgical procedure has a significant impact on perioperative risk and the amount of preparation required to perform anesthesia safely. For surgical procedures not associated with significant stress or a high incidence of perioperative myocardial ischemia or morbidity, the cost of the evaluation often exceeds any benefit from the information gained by preoperative assessment. Outpatient procedures, for example, cause little morbidity and mortality; in such patients, cardiovascular status rarely changes perioperative management unless the patient has unstable angina or overt congestive heart failure. In fact, 30-day mortality after outpatient surgery may actually be lower than that expected if the patient did not undergo surgery. In contrast, open surgery for vascular disease entails a high risk for morbidity and the potential for ischemia. Intra-abdominal, thoracic, and

MANAGEMENT OF POSTOPERATIVE ATRIAL TACHYARRHYTHMIAS

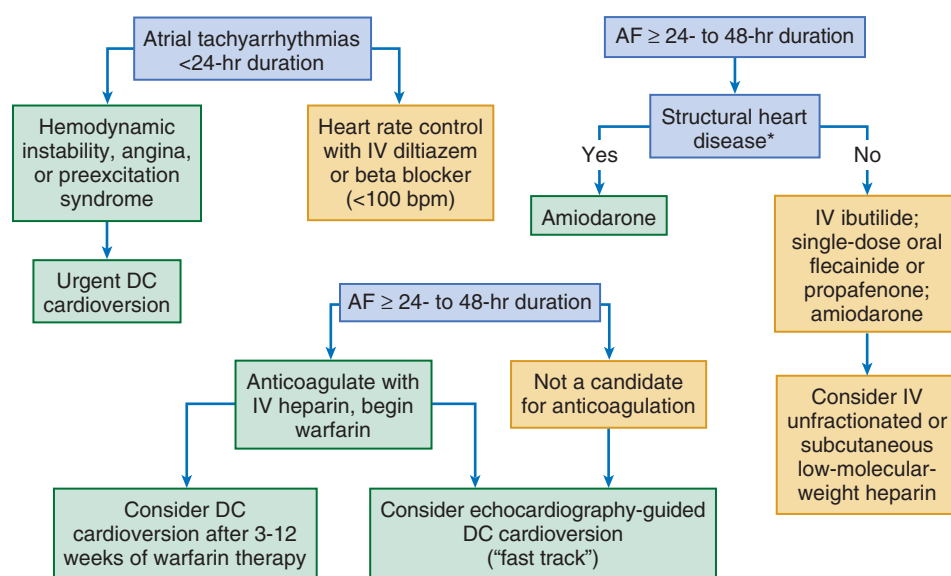

FIGURE 80-1 Proposed algorithm for the treatment of postoperative atrial tachyarrhythmias. *Structural heart disease is defined as the presence of one of the following: left ventricular hypertrophy with wall thickness greater than 1.4 cm, mitral valve disease, coronary artery disease, or heart failure. AF = atrial fibrillation/flutter; bpm = beats/minute; DC = direct current. (From Amar D: Perioperative atrial tachyarrhythmias. *Anesthesiology* 97:1618, 2002.)

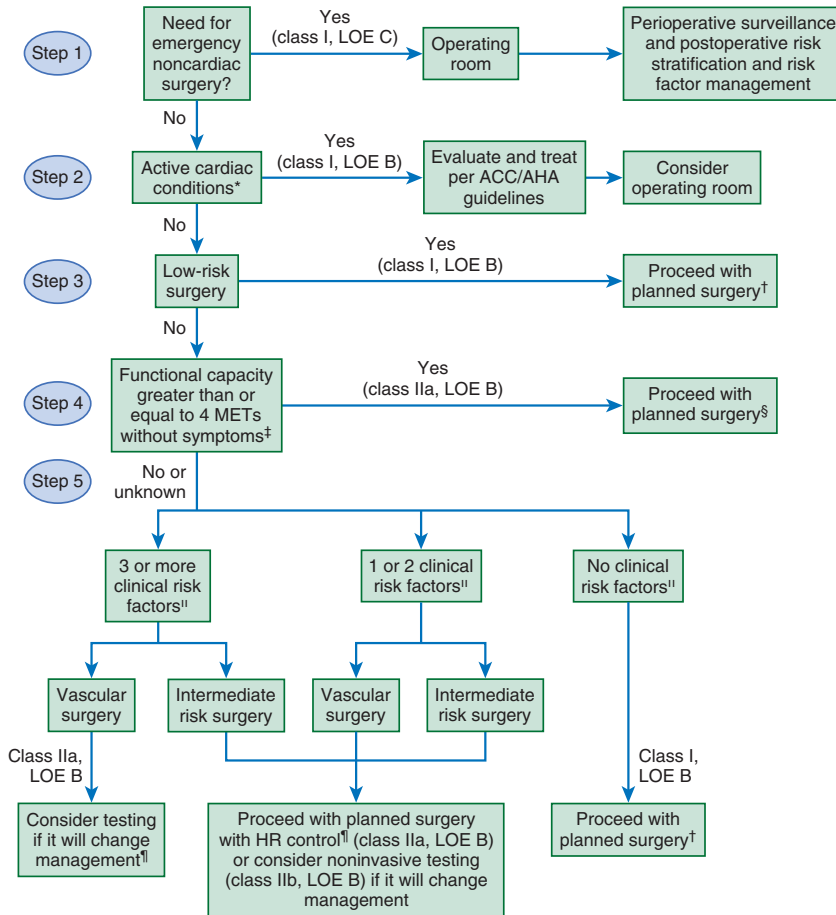

FIGURE 80-2 One of multiple algorithms proposed by the ACCF/AHA Task Force on Perioperative Evaluation of Cardiac Patients Undergoing Noncardiac Surgery for decisions regarding the need for further evaluation. This algorithm incorporates the class of recommendation and the strength of evidence for each step. *See Table 80-1 for active cardiac conditions. †See class III recommendations in Section 5.2.3. Noninvasive Stress Testing in the guidelines. ‡See Table 80-2 for estimated MET level equivalent. §Noninvasive testing may be considered before surgery in specific patients with risk factors if it will change management. ¶Clinical risk factors include ischemic heart disease, compensated or previous heart failure, diabetes mellitus, renal insufficiency, and cerebrovascular disease. ¶¶Consider perioperative beta blockade (see Table 11 in the source article listed below for populations in which this has been shown to reduce cardiac morbidity/mortality. LOE = level of evidence; MET = metabolic equivalent. (From Fleisher LA, Beckman JA, Brown KA, et al: 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation* 120:e169, 2009.)

orthopedic procedures are associated with intermediate risk (Table 80-3). Endovascular procedures fall into this intermediate-risk category on the basis of their associated perioperative morbidity and mortality, although long-term survival appears to be similar to that in patients who undergo open procedures.

In addition to the risk related to the surgical procedure itself, risk is also correlated with the surgical volume in a given center. Several studies have demonstrated differential mortality rates in both cancer and vascular surgery, with higher mortality occurring in low-volume centers, although recent studies have demonstrated that low-volume centers may also have low mortality rates if proper care systems are in place. Surgical mortality rates may therefore be institution specific, which may influence the decision to perform further perioperative evaluations and interventions.

The ACCF/AHA Task Force for Guidelines for Perioperative Cardiovascular Evaluation and Management for Noncardiac Surgery presented their recommendations in algorithmic form as a framework for determining which patients are candidates for cardiac testing (Fig. 80-2). Given the availability of the evidence, the writing committee chose to include the level of the recommendations and strength of evidence for each of the pathways.

Step 1: The consultant should determine the urgency of performing noncardiac surgery. In many cases, patient- or surgery-specific factors dictate an obvious strategy (e.g., emergency surgery) that may not allow further cardiac assessment or treatment.

Step 2: Does the patient have an active cardiac condition? In patients being considered for elective noncardiac surgery, the presence of unstable coronary disease, decompensated heart failure, or severe arrhythmia or valvular heart disease usually leads to cancellation or delay of surgery until the cardiac problem has been clarified and treated appropriately. Unstable coronary syndromes include previous MI with evidence of substantial ischemic risk as determined by clinical symptoms or noninvasive study, unstable or severe angina, and new or poorly controlled ischemia-mediated heart failure. Depending on the results of tests or interventions and the risk inherent in delaying surgery, it may be appropriate to proceed to the planned surgery with maximal medical therapy.

Step 3: Is the patient undergoing low-risk surgery? Interventions based on cardiovascular testing in stable patients rarely result in a change in management, and it is appropriate to proceed with the planned surgical procedure.

Step 4: Does the patient have moderate functional capacity without symptoms? In highly functional asymptomatic patients, management rarely changes on the basis of the results of any further cardiovascular testing, and it is therefore appropriate to proceed with the planned surgery. If the patient has poor functional capacity, is symptomatic, or has unknown functional capacity, the presence of clinical risk factors will determine the need for further evaluation. If the patient has no clinical risk factors, it is appropriate to proceed with the planned surgery, and no further change in management is indicated.

If the patient has one or two clinical risk factors, it is reasonable either to proceed with the planned surgery or to consider testing if it will change management. In patients with three or more clinical risk factors who are to undergo vascular surgery, recent studies suggest that testing should be considered only if it would change management. In nonvascular surgical procedures in which perioperative morbidity ranges from 1% to 5% (intermediate-risk surgery), data are insufficient to determine the best strategy (proceeding with the planned surgery with tight HR control with beta blockade or further cardiovascular testing if it will change management).

Falcone and colleagues, as cited in the guidelines, performed a small, randomized trial of 99 patients undergoing elective vascular surgery.² Patients at low or intermediate clinical risk were randomly assigned to testing or no testing, with no differences being found in perioperative or long-term outcomes. The vast majority of these patients were highly functional and received beta blockers perioperatively, thus suggesting that exercise capacity can help determine the need for further diagnostic testing preoperatively.

Poldermans and associates (the DECREASE studies) randomly assigned 770 intermediate-risk patients to cardiac stress testing (n = 386) or to no testing.¹⁶ Those with extensive stress-induced ischemia were considered for revascularization, with the choice of procedure being at the discretion of the primary physician. HR was tightly controlled with beta blockers in all patients. Patients assigned to no testing had an incidence of cardiac death or MI at 30 days after surgery similar to that in patients assigned to testing.

TABLE 80-1 Active Cardiac Conditions for Which Patients Should Undergo Evaluation and Treatment Before Noncardiac Surgery (Class I; Level of Evidence: B)

CONDITION	EXAMPLES
Unstable coronary syndromes	Unstable or severe angina* (CCS class III or IV) [†] Recent MI [‡]
Decompensated HF (NYHA functional class IV; worsening or new-onset HF)	
Significant arrhythmias	High-grade atrioventricular block Mobitz II atrioventricular block Third-degree atrioventricular heart block Symptomatic ventricular arrhythmias Supraventricular arrhythmias (including atrial fibrillation) with an uncontrolled ventricular rate (HR >100 beats/min at rest) Symptomatic bradycardia Newly recognized ventricular tachycardia
Severe valvular disease	Severe aortic stenosis (mean pressure gradient >40 mm Hg, aortic valve area <1.0 cm ² , or symptomatic) Symptomatic mitral stenosis (progressive dyspnea on exertion, exertional presyncope, or HF)

*According to Campeau L, Enjalbert M, Lesperance J, et al: Atherosclerosis and late closure of aortocoronary saphenous vein grafts: Sequential angiographic studies at 2 weeks, 1 year, 5 to 7 years, and 10 to 12 years after surgery. *Circulation* 68(Suppl II):1, 1983.

[†]May include "stable" angina in patients who are unusually sedentary.

[‡]The American College of Cardiology National Database Library defines recent MI as more than 7 days but 1 month or less (within 30 days).

CCS = Canadian Cardiovascular Society; HF = heart failure; MI = myocardial infarction; NYHA = New York Heart Association.

TABLE 80-2 Estimated Energy Requirements for Various Activities

CAN YOU ...	
1 MET	Take care of yourself? Eat, dress, or use the toilet? Walk indoors around the house? Walk a block or two on level ground at 2-3 mph (3.2-4.8 kph)?
4 METs	Do light work around the house such as dusting or washing dishes? Climb a flight of stairs or walk up a hill? Walk on level ground at 4 mph (6.4 kph)? Run a short distance? Do heavy work around the house such as scrubbing floors or lifting or moving heavy furniture? Participate in moderate recreational activities such as golf, bowling, dancing, doubles tennis, or throwing a baseball or football?
>10 METs	Participate in strenuous sports such as swimming, singles tennis, football, basketball, or skiing?

kph = kilometers per hour; MET = metabolic equivalent; mph = miles per hour.

TABLE 80-3 Cardiac Risk* Stratification for Noncardiac Surgical Procedures

RISK STRATIFICATION	EXAMPLES OF PROCEDURES
High (reported cardiac risk often >5%)	Aortic and other major vascular surgery Peripheral vascular surgery
Intermediate (reported cardiac risk generally 1-5%)	Intraperitoneal and intrathoracic surgery Carotid endarterectomy Head and neck surgery Orthopedic surgery Prostate surgery
Low [†] (reported cardiac risk generally <1%)	Endoscopic procedures Superficial procedure Cataract surgery Breast surgery Ambulatory surgery

*Combined incidence of cardiac death and nonfatal MI.

[†]These procedures do not generally require further preoperative cardiac testing. From Fleisher LA, Beckman JA, Brown KA, et al: 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation* 120:e169, 2009.

TESTS TO IMPROVE IDENTIFICATION AND DEFINITION OF CARDIOVASCULAR DISEASE

Several noninvasive diagnostic methods can be used to evaluate the extent of CAD before noncardiac surgery. The exercise electrocardiogram has traditionally been used to evaluate individuals for the presence of CAD, but as outlined earlier, patients with excellent exercise tolerance in daily life will rarely benefit from further testing. Patients with poor exercise capacity, in contrast, may not achieve an adequate HR and BP for diagnostic purposes on electrocardiographic stress tests. Such patients often require concomitant imaging.

Many high-risk patients either cannot exercise or have contraindications to exercise (e.g., patients with claudication or an abdominal aortic aneurysm who are undergoing vascular surgery, both of which have a high rate of perioperative cardiac morbidity). Pharmacologic stress testing has therefore become popular, particularly as a preoperative test in patients undergoing vascular surgery. Several studies have shown that the presence of a redistribution defect on dipyridamole or adenosine thallium or sestamibi imaging in patients undergoing peripheral vascular surgery is predictive of postoperative cardiac events. Pharmacologic stress imaging is best used in patients at moderate clinical risk. Several strategies may increase the predictive

value of such tests. The redistribution defect can be quantitated, with larger areas of defect being associated with increased risk. Additionally, both increased lung uptake and dilation of the left ventricular cavity are indicative of ventricular dysfunction with ischemia. Several investigative groups have demonstrated that delineation of low-risk and high-risk thallium scans (larger area of defect, increased lung uptake, and dilation of the left ventricular cavity) markedly improves the test's predictive value. They showed that patients with high-risk thallium scans have particularly increased risk for perioperative morbidity and long-term mortality.

Stress echocardiography has also been used widely as a preoperative test. One advantage of this test is that it dynamically assesses myocardial ischemia in response to increased inotropy and HR, stimuli relevant to the perioperative period. The presence of new wall motion abnormalities occurring at a low HR is the best predictor of increased perioperative risk, with large areas of contractile dysfunction having secondary importance. As part of the DECREASE studies, Boersma and colleagues (as cited in the guidelines) assessed the value of dobutamine stress echocardiography with respect to the extent of wall motion abnormalities and the ability of preoperative treatment with beta blockers to attenuate risk in patients undergoing major aortic surgery.² They assigned 1 point for each of the following characteristics: age older than 70 years, current angina, MI, congestive heart failure, previous cerebrovascular disease, diabetes mellitus, and renal failure. As the total number of clinical risk factors increases, perioperative cardiac event rates also increase. Furthermore, with a high-risk score, abnormal findings on an echocardiogram predicted higher risk.

So which diagnostic test should be used for preoperative assessment of risk? Several groups have recently published meta-analyses examining various preoperative diagnostic tests. Such studies report good predictive values for ambulatory electrocardiographic monitoring, radionuclide angiography, dipyridamole-thallium imaging, and dobutamine stress echocardiography. Shaw and colleagues, as cited in the guidelines, also demonstrated excellent predictive values for dipyridamole thallium imaging and dobutamine stress echocardiography.² Beattie and colleagues, also cited in the guidelines, performed a meta-analysis of 25 stress echocardiography studies and 50 thallium imaging studies.² The likelihood ratio for stress echocardiography was more indicative of a postoperative cardiac event than that for thallium imaging (likelihood ratio of 4.09; 95% confidence interval [CI], 3.21 to 6.56; versus a likelihood ratio of 1.83; 95% CI, 1.59 to 2.10; $P < 0.001$). The difference was attributable to fewer false-negative stress echocardiograms. A moderate to large abnormality found by either test predicted postoperative MI and death.

Institutional expertise is an important determinant with respect to the choice of preoperative testing. The relevant clinical questions also influence the choice of test. For example, if valve function or myocardial thickness is of interest, echocardiography has advantages over perfusion imaging. Stress nuclear imaging may have slightly higher sensitivity, but stress echocardiography may have fewer false-positive results. The role of newer imaging modalities such as magnetic resonance imaging, multislice computed tomography, coronary calcium scores, and positron emission tomography in preoperative risk assessment is rapidly evolving.

OVERVIEW OF ANESTHESIA FOR CARDIAC PATIENTS UNDERGOING NONCARDIAC SURGERY

Three classes of anesthetics exist: general, regional, and local/sedation or monitored anesthesia care (MAC). General anesthesia can be defined best as a state that includes unconsciousness, amnesia, analgesia, immobility, and attenuation of autonomic responses to noxious stimulation, and it can be achieved with inhalational agents, intravenous agents, or a combination of these (frequently termed a "balanced technique"). Additionally, contemporary general anesthesia does not always require an endotracheal tube. Laryngoscopy and intubation were traditionally considered the time of greatest stress

and risk for myocardial ischemia, but extubation may actually engender greater risk. Alternative methods for delivering general anesthesia use a mask or a laryngeal mask airway—a device that fits above the epiglottis and does not require laryngoscopy or intubation.

Five inhalational anesthetic agents (in addition to nitrous oxide) are currently approved in the United States, although enflurane and halothane are rarely used today. All inhalational agents have reversible myocardial depressant effects and lead to decreases in myocardial oxygen demand. The degree to which they depress cardiac output depends on their concentration, their effects on systemic vascular resistance, and their effects on baroreceptor responsiveness; agents therefore differ in their specific effects on HR and BP. Isoflurane causes negative inotropic effects and potent vascular smooth muscle relaxation and has minimal effects on baroreceptor function. Desflurane has the fastest onset and is commonly used in the outpatient setting. The onset and offset of action of sevoflurane are intermediate to those of isoflurane and desflurane; its major advantage is an extremely pleasant smell, which makes it the agent of choice in children.

Issues have arisen regarding the safety of inhalational agents in patients with CAD. Several large-scale, randomized and nonrandomized studies of inhalational agents in patients undergoing coronary artery bypass grafting (CABG) have not demonstrated any increased incidence of myocardial ischemia or infarction in patients receiving inhalation agents versus narcotic-based techniques.

The safety of desflurane has also raised some concerns. This agent can cause airway irritability and its use has led to tachycardia in volunteer studies. In a large-scale study comparing a narcotic-based anesthetic with a desflurane-based anesthetic, the desflurane group had a significantly higher incidence of myocardial ischemia, although there was no difference in the incidence of MI. Including a narcotic with desflurane can avoid this tachycardia. One randomized trial of patients at high risk for cardiovascular disease compared sevoflurane with isoflurane. No differences in the incidence of myocardial ischemia were observed, but the study was underpowered to detect any difference in the incidence of MI. Overall, at this time there does not appear to be any best inhalational anesthetic for patients with CAD.

The use of inhalational anesthetics in patients with CAD has theoretical advantages. Several investigative groups have demonstrated in vitro and in animals that these agents have protective effects on myocardium similar to that of ischemic preconditioning. This favorable effect on myocardial oxygen demand would serve to offset the theoretical effects of coronary steal in patients with chronic coronary occlusion.

High-dose narcotic techniques offer the advantages of hemodynamic stability and lack of myocardial depression. Narcotic-based anesthetics were frequently considered the "cardiac anesthesia" and were advocated for use in all high-risk patients, including those undergoing noncardiac surgery. The disadvantage of these traditional high-dose narcotic techniques is the requirement for postoperative ventilation. An ultrashort-acting narcotic (remifentanyl) was introduced into clinical practice and obviated the need for prolonged ventilation. This agent can assist in early extubation of patients undergoing cardiac surgery and may aid in managing short periods of intense intraoperative stress in high-risk patients.

Despite the theoretical advantages of a high-dose narcotic technique, several large-scale trials in patients undergoing CABG showed no difference in survival or major morbidity in comparison to the inhalation-based technique. This observation has contributed to the abandonment of high-dose narcotics in much of cardiac surgery and to an emphasis on early extubation. Most anesthesiologists use a "balanced" technique involving the administration of lower doses of narcotics with an inhalational agent. This approach allows the anesthesiologist to derive the benefits of each of these agents while minimizing side effects.

The intravenous agent propofol is an alternative mode of delivering general anesthesia. An alkyl phenol that can be used for both induction and maintenance of general anesthesia, propofol can cause profound hypotension because of reduced arterial tone with no change in HR. Its major advantage is rapid clearance with few residual effects on awakening, but because it is expensive, its current use tends to be limited to operations of brief duration. Despite its hemodynamic effects, it has been used extensively to assist in early

extubation after CABG. Current evidence indicates that there is no single best general anesthetic technique for patients with CAD who are undergoing noncardiac surgery, which has led to abandonment of the concept of a “cardiac anesthetic.”

Spinal and Epidural Anesthesia

Regional anesthesia includes spinal, epidural, and peripheral nerve blocks, and each technique has advantages and risks. Peripheral techniques, such as brachial plexus or Bier blocks, offer the advantage of causing minimal or no hemodynamic effects. In contrast, spinal or epidural techniques can produce sympathetic blockade, which can reduce BP and slow the HR. Spinal anesthesia and lumbar or low thoracic epidural anesthesia can also evoke reflex sympathetic activation mediated above the level of blockade, which might lead to myocardial ischemia.

The primary clinical difference between epidural and spinal anesthesia is the ability to provide continuous anesthesia or analgesia via placement of an epidural catheter, as opposed to a single dose with spinal anesthesia, although some clinicians will place a catheter in the intrathecal space. Even though the speed of onset depends on the local anesthetic agent used, spinal anesthesia and its associated autonomic effects occur sooner than when the same agent is administered epidurally. A catheter, usually left in place for epidural anesthesia, permits titration of the agent. Epidural catheters can also be used postoperatively to provide analgesia.

A great deal of research has compared regional with general anesthesia for patients with CAD, particularly in those undergoing infringuinal bypass surgery. In one meta-analysis, overall mortality was reduced by approximately a third in patients allocated to neuraxial blockade, although the findings were controversial because most of the benefit was observed in older studies.¹⁷ Reductions in MI and renal failure also occurred. A recent large-scale study of regional versus general anesthesia in noncardiac surgery patients was unable to demonstrate a difference in outcome.

Monitored Anesthesia Care

MAC encompasses local anesthesia administered by the surgeon, with or without sedation. In a large-scale cohort study, MAC was associated with increased 30-day mortality when compared with general anesthesia in a univariate analysis, although it did not remain significant in multivariate analysis once patient comorbidity was taken into account. The major issue with MAC is the ability to adequately block the stress response because the tachycardia associated with inadequate analgesia may be worse than the potential hemodynamic effects of general or regional anesthesia. Since the introduction of newer, short-acting intravenous agents, general anesthesia can now be administered essentially without an endotracheal tube. This allows the anesthesiologist to provide intense anesthesia for short or peripheral procedures without the potential effects of endotracheal intubation and extubation and therefore blurs the distinction between general anesthesia and MAC. In an analysis of closed insurance claims, Bhananker and colleagues demonstrated a high incidence of respiratory complications with MAC.¹⁸

Intraoperative Hemodynamics and Myocardial Ischemia

Over the last two decades, numerous studies have explored the relationship between hemodynamics and perioperative ischemia and MI. Tachycardia is the strongest predictor of perioperative ischemia. Although traditionally an HR higher than 100 beats/min defines tachycardia, slower HRs may result in myocardial ischemia. As described later, control of HR with beta blockers decreases the incidence of myocardial ischemia and infarction. In the DECREASE studies, Feringa and colleagues demonstrated that HR control lowers the incidence of perioperative MI, with the greatest benefit being achieved if HR is controlled to less than 70 beats/min.¹⁹ Although some have expressed concern about beta blockers causing intraoperative hypotension in patients with CAD, no evidence supports this contention, although the POISE trial demonstrated that an acute beta-blockade protocol was associated with hypotension and a

higher rate of stroke in the metoprolol arm. During CABG, the vast majority of episodes of intraoperative ischemia do not correlate with hemodynamic changes. In the absence of tachycardia, hypotension is not associated with myocardial ischemia.

POSTOPERATIVE MANAGEMENT

Overview of the Postoperative Response to Surgery

Understanding the pathophysiology of perioperative cardiac events helps in determining the best approach to preoperative testing. A full discussion of the pathophysiology of perioperative MI has been published.²⁰ All surgical procedures cause a stress response, although the extent of the response depends on the extent of the surgery and the use of anesthetics and analgesics to reduce the response. The stress response can increase HR and BP, which can precipitate episodes of myocardial ischemia in areas distal to coronary artery stenoses. Prolonged myocardial ischemia (either prolonged individual episodes or prolonged cumulative duration of shorter episodes) can cause myocardial necrosis and perioperative MI and death. Identification of patients at high risk for coronary artery stenosis, through either the history or cardiovascular testing, can lead to the implementation of strategies to reduce morbidity as a result of supply-demand mismatches. Recent work with highly sensitive markers of myocardial damage has shown a high rate of cardiac injury even in the absence of frank infarction. In the POISE trial, 8.3% of the patients had an elevated cardiac biomarker without other evidence of infarction, whereas 5% also had a second confirmatory marker of MI.²¹

A major mechanism of MI in the nonoperative setting is plaque rupture in a noncritical coronary stenosis with subsequent coronary thrombosis (see Chapters 41 and 51). Inasmuch as the perioperative period is marked by tachycardia and a hypercoagulable state, plaque disruption and thrombosis may occur quite commonly. Because noncritical stenosis can furnish the nidus for coronary artery thrombosis, preoperative cardiac evaluation may fail to identify patients at risk before surgery, although HR control may decrease the propensity of the plaque to rupture. The areas distal to the noncritical stenosis would not be expected to have collateral coronary flow, and therefore any acute thrombosis may have a greater detrimental effect than it would in a previously severely narrowed vessel. If the postoperative MI is caused by a prolonged increase in myocardial oxygen demand in a patient with one or more critical fixed stenoses, preoperative testing would probably identify such a patient.

Evidence from several autopsy and postinfarction angiography studies after surgery supports both mechanisms. Ellis and colleagues demonstrated that a third of all patients sustained events in areas distal to noncritical stenoses. Dawood and associates, as cited in the guidelines, demonstrated that fatal perioperative MI occurs predominantly in patients with multivessel coronary disease, especially left main and three-vessel disease, but the severity of preexisting underlying stenosis did not predict the resulting infarct territory.² This analysis suggested that fatal events occurred primarily in patients with advanced fixed stenoses but that the infarct may result from plaque rupture in a mild or only moderately stenotic segment of the diseased vessel. Duvall and colleagues reviewed hospital records and coronary angiograms from patients who underwent noncardiac surgery complicated by perioperative MI from 1998 to 2006.²² The distribution of demand, thrombotic, and nonobstructive MI was 55%, 26%, and 19%, respectively. In contrast, Gualandro and colleagues found that almost 50% of patients with perioperative acute coronary syndromes have evidence of ruptured coronary plaque.²³ The evidence therefore supports a multifactorial cause.

Postoperative Intensive Care

Provision of intensive care by intensivists has now become a patient safety goal. Pronovost and coworkers performed a systematic review of the literature on physician staffing patterns and clinical outcomes in critically ill patients. They grouped ICU physician staffing into low-intensity (no intensivist or elective intensivist consultation) and

high-intensity (mandatory intensivist consultation or closed ICU [all care directed by an intensivist]) groups. High-intensity staffing was associated with lower hospital mortality in 16 of 17 studies (94%) and with a pooled estimate of the relative risk for hospital mortality of 0.71 (95% CI, 0.62 to 0.82). High-intensity staffing was associated with lower ICU mortality in 14 of 15 studies (93%) and with a pooled estimate of the relative risk for ICU mortality of 0.61 (95% CI, 0.50 to 0.75). High-intensity staffing reduced hospital LOS in 10 of 13 studies and reduced ICU LOS in 14 of 18 studies without case mix adjustment. High-intensity staffing was associated with reduced hospital LOS in 2 of 4 studies and lowered ICU LOS in both studies that adjusted for case mix. No study found increased LOS with high-intensity staffing after case mix adjustment. High-intensity versus low-intensity ICU physician staffing was associated with reduced hospital and ICU mortality and LOS.

Postoperative Pain Management

Postoperative analgesia may reduce perioperative cardiac morbidity. Because postoperative tachycardia and catecholamine surges probably promote myocardial ischemia and/or rupture of coronary plaque and because postoperative pain can produce tachycardia and increase catecholamines, effective postoperative analgesia may reduce cardiac complications. Postoperative analgesia may also reduce the hypercoagulable state. Epidural anesthesia may decrease platelet aggregability when compared with general anesthesia. Whether this decrease is related to intraoperative or postoperative management is unclear. In an analysis of Medicare claims data, the use of epidural analgesia (as determined by billing codes for postoperative epidural pain management) was associated with decreased risk for death at 7 days. Future research will focus on how best to deliver postoperative analgesia to maximize the potential benefits and reduce complications.

SURVEILLANCE AND IMPLICATIONS OF PERIOPERATIVE CARDIAC COMPLICATIONS

The optimal and most cost-effective strategy for monitoring high-risk patients for major morbidity after noncardiac surgery is unknown. Myocardial ischemia and infarctions that occur postoperatively are usually silent, most likely because of the confounding effects of analgesics and postoperative surgical pain. The MB fraction of creatine kinase (CK-MB) is also less specific for myocardial necrosis postoperatively because this marker can rise during aortic or peripheral arterial surgery and after mesenteric ischemia. Further confounding the issue, most perioperative MIs do not cause ST-segment elevation, and less specific ST-T wave changes are common after surgery with or without MI. These considerations therefore render the diagnosis of perioperative MI particularly difficult to make.

A marked elevation in mortality associated with postoperative MI provides continuing impetus for improved methods of detection. Biomarkers may help identify myocardial necrosis. Lee and colleagues, as cited in the guidelines, measured CK-MB and troponin T levels in 1175 patients undergoing noncardiac surgery and created receiver operating characteristic (ROC) curves.² They found that troponin T had similar efficacy as CK-MB in diagnosing perioperative MI but significantly better correlation with major cardiac complications developing after acute MI. Metzler and colleagues (as cited in the guidelines) examined the sensitivity of the troponin assay at variable cutoff levels—a value greater than 0.6 ng/mL demonstrated a positive predictive value of 87.5% and a negative predictive value of 98%.² Le Manach and coworkers (as cited in the guidelines) studied 1152 consecutive patients who underwent abdominal infrarenal aortic surgery and identified four patterns of cardiac troponin I (cTnI) release after surgery.² One group did not have any abnormal levels, whereas a second group had only mild elevations in cTnI. Interestingly, two groups demonstrated elevations in cTnI consistent with perioperative MI. One had acute (<24 hour) and early elevations in cTnI above threshold, and the other demonstrated prolonged low levels of cTnI release, followed by a delayed (>24 hour) elevation in cTnI. The authors

suggest that these two different patterns represent two distinct pathophysiologies: acute coronary occlusion for early morbidity and prolonged myocardial ischemia for late events. Mohler and colleagues evaluated cTnI and CK-MB in 784 high-risk vascular surgery patients on the day of surgery and at 24 hours, 72 hours, and 120 hours postoperatively. They reported a sensitivity of 51% and a specificity of 91% for the defined cardiovascular event by using an ROC-defined cut point for CK-MB of 3.1 ng/mL.²⁴

In the VISION (Vascular Events in Noncardiac Surgery Cohort Evaluation) study, 15,133 subjects undergoing noncardiac surgery had troponin T measurements performed between 6 and 12 hours postoperatively and on postoperative days 1, 2, and 3.²⁵ Troponin T levels above the baseline level of 0.01 ng/mL or lower were associated with increased rates of 30-day mortality. Indeed, a troponin T level of 0.02 ng/mL was associated with more than a twofold risk for death. With a troponin T level of 0.3 ng/mL or higher, the hazard ratio for death increased to more than 10-fold above that in patients without any elevation in troponin. Mortality was 16.9% with a troponin T level of 0.3 ng/mL or higher as opposed to 1% in the group without troponin elevation. Although troponin T levels stratified the rate of mortality across a low spectrum of positive levels, it could not predict the cause of death. Both vascular and nonvascular death increased similarly with increasing troponin T levels, and more than half of all deaths were due to nonvascular causes. An elevated troponin T level thus provides adverse prognostication without direction for appropriate therapy.

Recent studies have evaluated brain natriuretic peptide (BNP) in the perioperative period. Mahla and colleagues measured preoperative and postoperative N-terminal pro-BNP (NT-pro-BNP) in 218 vascular surgery patients. Using ROC analysis—defined cut points, patients with elevated NT-pro-BNP had almost a 20-fold in-hospital and 5-fold long-term risk for cardiac events.²⁶ Goei and associates evaluated the predictive capacity of preoperative levels of NT-pro-BNP in 356 vascular surgery patients and found that elevations in BNP were associated with adverse 30-day cardiovascular events in subjects with normal renal function but not in those with severe renal impairment.²⁷ In a meta-analysis of seven prospective observational studies, BNP or NT-pro-BNP above the ROC-determined optimal threshold was associated with marked increases in 30-day and intermediate-term cardiac death, nonfatal MI, and major adverse cardiac events.²⁸ A subsequent meta-analysis demonstrated that preoperative BNP measurement independently predicted perioperative cardiovascular events in studies that considered only the outcomes of death, cardiovascular death, or MI (odds ratio [OR], 44.2; 95% CI, 7.6 to 257.0; $I^2 = 51.6\%$), and in studies that included other outcomes, the OR was 14.7 (95% CI, 5.7 to 38.2; $I^2 = 62.2\%$).²⁹

Traditionally, perioperative MI has been associated with 30% to 50% short-term mortality, but recent series have reported a fatality rate of less than 20% for perioperative MI. Studies from the 1980s suggested a peak incidence on the second and third postoperative days. Badner and colleagues, using troponin I as a marker for MI, suggested that the highest incidence occurred during the immediate and first postoperative days, as confirmed in other studies. The finding that hypotension in the postanesthetic care unit best predicted release of troponin suggests a hemodynamic rather than plaque rupture event (type 2 versus type 1 MI). Thus the change is probably related to more robust surveillance methods, not to a fundamental shift in how or when myocardial ischemia or infarction occurs.

Increasing evidence has associated perioperative MI or biomarker elevation with worse long-term outcome. Lopez-Jimenez and colleagues, as cited in the guidelines, found that abnormal troponin T levels were associated with an increased incidence of cardiovascular complications within 6 months of surgery.² Kim and associates (as cited in the guidelines) studied perioperative troponin I levels in 229 patients undergoing aortic or infrainguinal vascular surgery or lower extremity amputation.² Twenty-eight patients (12%) had postoperative troponin I levels higher than 1.5 ng/mL, which was associated with a 6-fold increased risk for 6-month mortality and a 27-fold increased risk for MI. Furthermore, they observed a relationship between troponin I concentration and mortality. Landesberg and coworkers, as cited in the guidelines, demonstrated that postoperative CK-MB and troponin, even at low cutoff levels, are independent and complementary predictors of long-term mortality after major vascular surgery.² Mahla and colleagues have also

demonstrated that elevations in BNP are associated with a fivefold increased long-term risk for cardiac events.²⁶ The appropriate use of screening biomarkers in current preoperative risk assessment algorithms remains unstudied.

STRATEGIES TO REDUCE THE CARDIAC RISK ASSOCIATED WITH NONCARDIAC SURGERY

Surgical Revascularization

Some have suggested coronary revascularization as a means of reducing the perioperative risk related to noncardiac surgery. Retrospective evidence indicates that previous successful preoperative revascularization may decrease postoperative cardiac risk by twofold to fourfold in patients undergoing elective vascular surgery. The strongest evidence comes from the CASS (Coronary Artery Surgery Study) registry, which enrolled patients from 1978 to 1981, an era that antedates many of the current therapies shown to be effective for reducing coronary events.² Operative mortality in patients who underwent CABG before noncardiac surgery was 0.9%, but it was significantly higher (2.4%) in patients without previous CABG; a 1.4% mortality rate was associated with the CABG procedure itself. As cited in the guidelines, Eagle and coauthors reported a long-term analysis of patients entered into the CASS registry and assigned to medical or surgical therapy for CAD of more than 10 years' duration; they subsequently underwent 3368 noncardiac operations in the years following assignment of coronary treatment.² Intermediate-risk surgery such as abdominal, thoracic, or carotid endarterectomy was associated with a combined morbidity and mortality of 1% to 5%, with a small but substantial improvement in outcome in patients who had previously undergone revascularization. The most improvement in outcome occurred in patients undergoing major vascular surgery, such as abdominal or lower extremity revascularization. This observational analysis did not randomly assign patients, however, and reflects a different era in preventive strategies.

Several cohort studies have examined the benefit of percutaneous coronary intervention (PCI) before noncardiac surgery. Posner and colleagues, as cited in the guidelines, used an administrative data set of patients who underwent PCI and noncardiac surgery.² They matched patients with coronary disease undergoing noncardiac surgery with and without previous PCI and looked at cardiac complications. In this nonrandomized analysis, they noted a significantly lower rate of 30-day cardiac complications in patients who underwent PCI at least 90 days before the noncardiac surgery. PCI within 90 days of noncardiac surgery did not improve outcomes. The advent of drug-eluting stents requiring prolonged antiplatelet therapy may promote operative bleeding complications or increase subacute stent thrombosis if antiplatelet treatment is stopped perioperatively.

Several randomized trials have now addressed the value of both CABG and PCI in a subset of patients. McFalls and coauthors reported the results of a multicenter randomized trial in the Veterans Affairs Health System in which patients with documented CAD on coronary angiography, excluding those with left main disease or a severely depressed ejection fraction ($\leq 20\%$), were randomly assigned before elective major vascular surgery to CABG (59%) or PCI (41%) versus routine medical therapy.³⁰ At 2.7 years after randomization, mortality in the revascularization group did not differ significantly (22%) from that in the no-revascularization group (23%). Within 30 days after the vascular operation, postoperative MI, defined as elevated troponin levels, occurred in 12% of the revascularization group and in 14% of the no-revascularization group ($P = 0.37$). The authors suggested that coronary revascularization is not indicated in patients with stable CAD and that PCI or CABG for one- or two-vessel disease before noncardiac surgery does not prevent perioperative MI. In a reanalysis of the data, the completeness of revascularization was found to affect the rate of perioperative MI, with CABG being more effective than PCI. In the DECREASE studies, Poldermans and colleagues evaluated the role of coronary artery revascularization in 101 vascular surgery patients with three or more Lee Index risk factors and extensive stress-induced ischemia on a background of beta blocker therapy.

Revascularization improved neither 30-day nor 1-year outcomes ($P > 0.2$ for both),³¹ and only those with corrected left main CAD derived long-term benefit.³² Most recently, Garcia and colleagues analyzed both the randomly and nonrandomly assigned patients who underwent coronary angiography before vascular surgery: 4.6% of these patients had unprotected left main CAD. Only this subset of patients showed a benefit of preoperative coronary artery revascularization.³³

Monaco and associates studied 208 patients at moderate clinical risk who underwent major vascular surgery and were randomly allocated to either a "selective strategy" group in which coronary angiography was performed on the basis of results of noninvasive tests or to a "systematic strategy" group in which preoperative coronary angiography was systematically performed.³⁴ The strategy of routine coronary angiography had no effect on the short-term outcome, but the long-term outcome was improved in surgical patients with peripheral arterial disease at medium to high risk.

One issue in interpreting the results is that the length of time between coronary revascularization and noncardiac surgery most likely affects its protective effect and potential risks. Back and colleagues studied 425 consecutive patients undergoing 481 elective major vascular operations at an academic Veterans Affairs Medical Center.³⁵ Coronary revascularization was classified as recent (CABG, <1 year; percutaneous transluminal coronary angioplasty [PTCA], <6 months) in 35 cases, as previous (CABG, 1 to 5 years; PTCA, 6 months to 2 years) in 45 cases, and as remote (CABG, >5 years; PTCA, >2 years) in 48 cases. Patients with previous PTCA had similar outcomes as those after CABG. Significant differences in adverse cardiac events and mortality were found between patients with CABG performed within 5 years or PTCA within 2 years (6.3% and 1.3%, respectively), individuals with remote revascularization (10.4% and 6.3%, respectively), and nonrevascularized patients stratified at high risk (13.3% and 3.3%, respectively) or intermediate to low risk (2.8% and 0.9%, respectively). The authors concluded that previous coronary revascularization (CABG, <5 years; PTCA, <2 years) provides only modest protection against adverse cardiac events and mortality following major arterial reconstruction.

Coronary Stenting and Noncardiac Surgery

PCI using coronary stenting poses several special issues. Kaluza and colleagues, as cited in the guidelines, reported the outcome of 40 patients who underwent prophylactic coronary stent placement less than 6 weeks before major noncardiac surgery requiring general anesthesia.² They reported 7 MIs, 11 major bleeding episodes, and 8 deaths. All of the deaths and MIs, as well as 8 of the 11 bleeding episodes, occurred in patients subjected to surgery less than 14 days after stenting. Four patients died after undergoing surgery 1 day after stenting. Wilson and colleagues, as cited in the guidelines, reported on 207 patients in whom noncardiac surgery was performed within 2 months of stent placement.² Eight patients died or suffered an MI, and all of them were among the 168 patients who underwent surgery 6 weeks after stent placement. Vincenzi and coworkers (as cited in the guidelines) studied 103 patients and reported that the risk for a perioperative cardiac event was 2.11-fold greater in patients with recent stents (<35 days before surgery) than in those undergoing PCI more than 90 days before surgery.² These data pointed to the importance of delaying surgery after stenting, even though the investigators either continued antiplatelet drug therapy or only briefly interrupted it and all patients received heparin. Leibowitz and colleagues (as cited in the guidelines) studied 216 consecutive patients who underwent PCI within 3 months of noncardiac surgery (PTCA in 112 and stenting in 94).² A total of 26 patients (12%) died—13 in the stent group (14%) and 13 in the PTCA group (11%), a nonsignificant difference. The incidence of acute MI and death within 6 months did not differ significantly (7% and 14% in the stent group versus 6% and 11% in the PTCA group, respectively). Many more events occurred in the two groups when noncardiac surgery was performed within 2 weeks of PCI. On the basis of the accumulating data, elective noncardiac surgery after PCI—with or without stent placement—should be delayed for 4 to 6 weeks.

Drug-eluting stents may represent an even greater problem during the perioperative period. Emerging data from a series of recent analyses in the nonoperative setting and several perioperative case reports suggest that the risk for thrombosis continues for at least 1 year after insertion.² Several reports suggest that drug-eluting stents may represent an additional risk over a prolonged period (up to 12 months), particularly if the use of antiplatelet agents is discontinued.

Schouten's group retrospectively evaluated 192 patients who underwent noncardiac surgery after successful PCI for unstable CAD within 2 years of the procedure.³⁶ Drug-eluting stents accounted for 52% of the stents placed. Of the 192 patients, 30 underwent surgery before the recommended discontinuation of dual antiplatelet therapy for the particular stent (30 days for bare metal stents and up to 6 months for sirolimus-eluting stents). In patients in whom antiplatelet therapy was stopped before the required time for use of clopidogrel (early-surgery group), the incidence of death or nonfatal MI was 30.7% as compared with 0% in patients who continued antiplatelet therapy. The elevated risk for stent thrombosis and cardiovascular events, however, seems to abate over time. Godet and colleagues investigated the risk for postoperative adverse cardiovascular events at a mean of 14 months after placement of a drug-eluting stent in 96 consecutive patients and noted a 2% in-stent thrombosis rate.³⁷ More recently, Anwaruddin and associates determined the risk for postoperative complications in 481 patients after placement of a drug-eluting stent an average of 1.1 years before the operation. They reported a 9% risk for death, nonfatal MI, or stent thrombosis by 30 days.³⁸ In the EVENT (Evaluation of Drug-Eluting Stents and Ischemic Events) registry of 4637 consecutive patients, 4.4% underwent major noncardiac surgery in the ensuing year.³⁹ They reported a relative 27-fold increased rate of cardiovascular events in the week following surgery versus any other week after stent implantation, but the absolute rate was only 1.9%. Wijeyundera and colleagues evaluated 8116 patients who underwent noncardiac surgery in Ontario, Canada, and found that 34% had a coronary stent implanted within the 2 years before surgery.⁴⁰ Drug-eluting stents represented a third of the stents placed. Patients with bare metal stents implanted less than 45 days before surgery had a 6.7% cardiovascular event rate, which dropped to 2.6% with a stent implanted 45 to 180 days before surgery. Subjects with a drug-eluting stent had a 20.2% cardiovascular event rate in the first 45 days after stent implantation, and the rate became similar to that in subjects without stenting when the stent was implanted more than 180 days before surgery. In a Scotland-wide retrospective cohort analysis, perioperative death and ischemic cardiac events were much more common within the first 6 weeks after stent implantation than after 6 weeks, 42.4% versus 12.8%, respectively.⁴¹ The event rate was higher in patients who underwent revascularization because of acute coronary syndromes within 6 weeks, in whom it reached 65%. In contrast to other reports, no temporal differences were noted between the bare metal and drug-eluting stent groups.

A 2007 science advisory from the AHA, ACC, Society for Cardiovascular Angiography and Interventions, American College of Surgeons, and American Dental Association stressed the importance of 12 months of dual antiplatelet therapy after placement of a drug-eluting stent. This advisory also recommended postponing elective surgery for 1 year and, if surgery cannot be deferred, considering continuation of aspirin during the perioperative period in high-risk patients with drug-eluting stents. In patients with illness requiring more timely surgery, strategies for bridging the cessation of antiplatelet therapy until the procedure include the use of intravenous eptifibatide and tirofiban, but these strategies lack outcomes data. Hawn and associates examined the national Veterans Affairs data on coronary stent implantation in the context of noncardiac surgery.⁴² Among the 126,773 stent procedures performed between 2000 and 2010, 20.5% of the patients underwent noncardiac surgery within 2 years of their coronary procedures. The authors noted that after publication of the national guidelines recommending a delay in noncardiac surgery after stenting, the rate of surgery dropped from 16.7% to 10% in the 12 months after stent implantation.

A subsequent study by Hawn and colleagues⁴³ demonstrated that perioperative major adverse cardiac events were not associated with stent type or timing of surgery beyond 6 months after stent implantation. The authors suggest that the guidelines should be reevaluated.

Pharmacologic Interventions

Beta-Adrenergic-Blocking Agents

Beta-adrenergic-blocking agents have undergone extensive study in perioperative risk management, which has led to recent guidelines for their use in this context. Mangano and colleagues, as cited in the guidelines, administered atenolol or placebo beginning on the morning of surgery and continuing for 7 days postoperatively in a cohort of 200 patients with known CAD or risk factors for CAD who underwent high-risk noncardiac surgery.² They demonstrated a marked reduction in the incidence of perioperative myocardial ischemia, but no differences in the rate of perioperative MI. Survival improved markedly at 6 months in the atenolol group and continued for at least 2 years. The authors speculated that the lower incidence of myocardial ischemia resulted from less plaque destabilization, with a resultant reduction in subsequent MI or death in the 6 months after noncardiac surgery. Issues of randomization and uneven distribution of risk factors and treatment at baseline and on discharge with beta blockers may account for the findings, at least in part. Poldermans and colleagues studied the perioperative use of bisoprolol versus routine care in patients undergoing elective major vascular surgery as part of the DECREASE studies.² This medication was started at least 7 days preoperatively, titrated to achieve a resting HR lower than 60 beats/min, and continued postoperatively for 30 days. Bisoprolol reduced perioperative MI or cardiac death by almost 80% in this high-risk population. Because of the selection criteria, the efficacy of bisoprolol in the highest-risk group—those who would be considered for coronary revascularization or modification or cancellation of the surgical procedure—cannot be determined from this trial. Dunkelgrun and associates investigated the role of beta blockers in intermediate-risk noncardiac surgery patients (defined as predicted risk for a cardiac event of 1% to 6%) in an open-label, randomized trial.⁴⁴ Bisoprolol, titrated to an HR of 50 to 70 beats/min preoperatively and maintained during the hospitalization, reduced the rate of perioperative cardiac death and nonfatal MI. As noted earlier, data concerning the titrated use of beta blockers from Poldermans and colleagues have become uncertain.

Trial data do not offer unanimous support for the perioperative use of beta blockers without titration to HR and BP. Brady and colleagues, as cited in the guidelines, randomly assigned 103 patients without previous MI who were scheduled to undergo infrarenal vascular surgery to oral metoprolol or to placebo from admission until 7 days after surgery.² Perioperative metoprolol did not reduce 30-day cardiovascular events, but this study lacked adequate power. The study did show that metoprolol reduced the time from surgery to discharge. Lindenauer and coworkers retrospectively reviewed the records of 782,969 patients and determined who received treatment with a beta blocker during the first 2 hospital days.⁴⁵ The relationship between perioperative treatment with a beta blocker and the risk for death varied directly with cardiac risk; in the 580,665 patients with an RCRI score of 0 or 1, treatment was associated with no benefit and possible harm, whereas in the patients with an RCRI score of 2, 3, or 4 or higher, adjusted ORs for death in the hospital for the treated versus untreated patients were 0.88 (95% CI, 0.80 to 0.98), 0.71 (95% CI, 0.63 to 0.80), and 0.58 (95% CI, 0.50 to 0.67), respectively. A study of 497 vascular surgery patients randomly assigned to a fixed dose of metoprolol versus placebo demonstrated no difference in perioperative outcome.² A trial of metoprolol in diabetic patients without known CAD undergoing a diverse range of surgical procedures did not demonstrate difference in perioperative outcomes. In the POISE trial, Devereaux and colleagues randomly assigned 8351 high-risk patients undergoing noncardiac surgery to metoprolol succinate, 200 mg daily, or matching placebo.⁶ The long-acting metoprolol was administered at 100 mg 2 to 4 hours before surgery and within 6 hours after surgery and then at 200 mg daily thereafter. Active treatment with a beta blocker reduced the composite of cardiovascular death, nonfatal MI, and nonfatal cardiac arrest at 30 days after random assignment by 1.1% but increased mortality by 0.8% and stroke by 0.5%. To what can one attribute this signal of harm? In the trials in which beta blockers did not improve outcomes or worsened them, titration was limited or absent. Moreover, the use of long-acting medications may have worsened outcomes by limiting the physician's ability to modify treatment on the basis of the rapidly shifting perioperative environment.

In 2009 a focused update of the ACC/AHA guidelines on perioperative use of beta blockers modified previous recommendations based on recent evidence.² Continuation of beta blockers in patients undergoing surgery remains a class I recommendation. No other class I recommendations are stated. A new class III recommendation is that routine administration of high-dose beta blockers in the absence of dose titration is not useful and may be harmful to patients not currently taking beta blockers who are undergoing noncardiac surgery (Table 80-4).

Several pragmatic considerations pertain to the perioperative use of beta blockers in those not currently taking these agents. Several authors have recently demonstrated that most patients about to undergo noncardiac surgery and even vascular surgery have not started taking beta blockers. One concern of anesthesiologists is related to acute administration of beta blockers on the day of surgery. The combined effect of an acute decrease in HR and induction of anesthesia in a beta blocker naïve patient has anecdotally been associated with marked bradycardia and hypotension. Treatment of these events may lead to wide swings in HR and BP and less HR control than desired. The approach to the use of beta blockers thus depends on preoperative status, type of surgery, cardiac risk factors, and any results of cardiac stress testing. Ideally, therapy with beta blockers should be initiated more than 7 days in advance,⁴⁶ and

longer-acting agents such as atenolol or bisoprolol should be used. Analyzing a large data base, Redelmeier (as cited in the guidelines) demonstrated improved perioperative survival in patients given atenolol versus metoprolol.² If a patient is undergoing nonvascular or vascular surgery and has indications for therapy with a beta blocker independent of surgery but is not currently taking a beta blocker, initiation of beta blockade several days preoperatively by the internist, cardiologist, or other primary care provider is appropriate to ensure a stable level of the beta blocker on the day of surgery. If several days of therapy with a beta blocker cannot be achieved, the potential risks associated with new-onset therapy during induction of general, epidural, or spinal anesthesia may outweigh the benefits of beginning drug therapy on the morning of surgery. Because the study by Mangano did not demonstrate any difference in in-hospital outcome and the approach of Raby and colleagues demonstrated similar efficacy with respect to perioperative ischemia, we suggest inducing general anesthesia or providing regional anesthesia before starting therapy with beta blockers. Intravenous esmolol or metoprolol administration can manage any tachycardia that may arise during induction. After adequate anesthesia and analgesia are achieved, the HR should be controlled and maintained below 70 beats/min.

Statin Therapy

In addition to their cholesterol-lowering properties, statins have anti-inflammatory and potential long-term plaque-stabilizing properties. Given the potential mechanisms of perioperative MI, statins have theoretical benefits. Poldermans and colleagues performed a case-control study of 2816 patients who underwent major vascular surgery from 1991 to 2000. Patients receiving statin therapy experienced less postoperative MI than did controls (8% versus 25%; $P < 0.001$).² The adjusted OR for perioperative mortality in statin users as compared with nonusers was 0.22 (95% CI, 0.10 to 0.47). Lindenauer and colleagues, as cited in the guidelines, used administrative data to study a cohort of 780,591 patients; 77,082 (9.87%) received lipid-lowering therapy perioperatively, and 23,100 (2.96%) died during hospitalization.² Via multivariate modeling and propensity matching, the number needed to treat to prevent a postoperative death was 85 (95% CI, 77 to 98) and varied from 186 in patients at lowest risk to 30 in those with an RCRI score of 4 or higher. Durazzo and colleagues, as cited in the guidelines, randomly assigned 100 patients to receive 20 mg atorvastatin or placebo once a day for 45 days.² The placebo group had more than a three times higher incidence of cardiac events (26%) than the treated group did (8%; $P < 0.031$). Patients treated with atorvastatin exhibited a significant lower rate of cardiac events within 6 months after vascular surgery than the placebo group did ($P < 0.018$). In DECREASE IV, Dunkelgrun and colleagues used a 2 × 2 factorial design to evaluate the administration of high-dose fluvastatin and a beta blocker to intermediate-risk patients and noted nonsignificant reductions in cardiovascular death and MI.⁴⁴ Accumulating evidence suggests that statin therapy should be continued during the perioperative period. Le Manach and associates evaluated the effect of statin discontinuation in a vascular surgery population.⁴⁷ When compared with a control population, discontinuation of statins was associated with more than a twofold increase in troponin elevation, whereas continuation reduced the rate of troponin release by more than 40%. Indeed, consideration should be given to starting statin therapy in high-risk patients because they probably merit this treatment even without surgery.

Nitroglycerin

Only two randomized trials have evaluated the potential protective effect of prophylactic nitroglycerin in reducing perioperative cardiac complications after noncardiac surgery. In a small study by Coriat and colleagues involving patients undergoing carotid endarterectomy, high-dose (1 µg/kg/min) nitroglycerin was more effective than low-dose (0.5 µg/kg/min) nitroglycerin in reducing the incidence of myocardial ischemia, but MI did not occur in either group. The anesthetic used in this study was an oxygen-pancuronium-fentanyl method, and therefore inhalational agents were not administered. Dodds studied nitroglycerin versus placebo in a balanced anesthetic technique and

TABLE 80-4 Recommendations for Perioperative Therapy with Beta Blockers

Class I
1. Beta blockers should be continued in patients undergoing surgery who are receiving them for treatment of conditions with ACCF/AHA class I guideline indications for the drugs. (<i>Level of evidence: C</i>)
Class IIa
1. Beta blockers titrated to HR and BP are probably recommended for patients undergoing vascular surgery who are at high cardiac risk because of CAD or the finding of cardiac ischemia on preoperative testing. (<i>Level of evidence: B</i>)
2. Beta blockers titrated to HR and BP are reasonable for patients in whom preoperative assessment for vascular surgery identifies high cardiac risk, as defined by the presence of more than one clinical risk factor.* (<i>Level of evidence: C</i>)
3. Beta blockers titrated to HR and BP are reasonable for patients in whom preoperative assessment identifies CAD or high cardiac risk, as defined by the presence of more than one clinical risk factor,* who are undergoing intermediate-risk surgery. (<i>Level of evidence: B</i>)
Class IIb
1. The usefulness of beta blockers is uncertain for patients who are undergoing either intermediate-risk procedures or vascular surgery and in whom preoperative assessment identifies a single clinical risk factor in the absence of CAD.* (<i>Level of evidence: C</i>)
2. The usefulness of beta blockers is uncertain in patients undergoing vascular surgery with no clinical risk factors who are not currently taking such agents. (<i>Level of evidence: B</i>)
Class III
1. Beta blockers should not be given to patients undergoing surgery who have absolute contraindications to beta blockade. (<i>Level of evidence: C</i>)
2. Routine administration of high-dose beta blockers in the absence of dose titration is not useful and may be harmful to patients not currently taking them who are undergoing noncardiac surgery. (<i>Level of evidence: B</i>)

*Clinical risk factors include a history of ischemic heart disease, history of compensated or previous heart failure, history of cerebrovascular disease, diabetes mellitus, and renal insufficiency (defined in the RCRI as a preoperative serum creatinine level of 2 mg/dL).

From Fleisher LA, Beckman JA, Brown KA, et al: 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation* 120:e169, 2009.

reported no difference in rates of myocardial ischemia or infarction. Taken together, the evidence suggests that prophylactic nitroglycerin does not reduce the incidence of perioperative cardiac morbidity, although neither trial was powered to detect a modest benefit of nitroglycerin. Because prophylactic nitroglycerin has considerable hemodynamic effects and is not known to prevent MI or cardiac death, the data do not support its routine use, although nitroglycerin can help in management if myocardial ischemia should develop.

Other Medications

Recently, results of PeriOperative ISchemic Evaluation-2 (POISE 2) were published. This was a blind, randomized trial with a 2-by-2 factorial design to allow separate evaluation of low-dose clonidine versus placebo and low-dose aspirin versus placebo in 10,010 patients with, or at risk for, atherosclerotic disease who were undergoing noncardiac surgery. Low-dose clonidine did not reduce the rate of death or nonfatal myocardial infarction, but was associated with an increased risk of clinically important hypotension and nonfatal cardiac arrest.⁴⁸ Administration of aspirin was not associated with any difference in the rate of death or nonfatal myocardial infarction, but increased the risk of major bleeding.⁴⁹

Nonpharmacologic Interventions

Temperature

Frank and colleagues, as cited in the guidelines, completed a randomized trial of regional versus general anesthesia for lower extremity vascular bypass procedures and noted an association between hypothermia (temperature <35°C) and myocardial ischemia.² They subsequently performed a trial in 300 high-risk patients undergoing a diverse range of intermediate- and high-risk procedures in which patients were randomly assigned to maintenance of normothermia or routine care. They observed a significantly reduced incidence of perioperative cardiac morbidity and mortality within 24 hours of surgery in the group that was kept normothermic.

Electrocardiographic, Hemodynamic, and Echocardiographic Monitoring

Multiple studies have demonstrated the predictive value of correlating perioperative ST-segment changes and major cardiac events, as described earlier. Furthermore, the duration (cumulative or continuous) of perioperative ST changes is strongly predictive of poor outcomes. ST-segment monitoring has therefore become standard during the intraoperative and ICU periods for high-risk patients. However, ST-segment changes may also develop in patients at low to moderate risk. These changes may not reflect true myocardial ischemia, as suggested in a recent series.

Postoperative patients may have the greatest risk for a cardiac event when on the ward and unmonitored. Few studies have tested the efficacy of ST-segment telemetric monitoring during the perioperative period. The issue of whether early treatment of prolonged ST-segment changes improves outcomes in this situation remains unresolved.

Much controversy surrounds the value of pulmonary artery catheterization for noncardiac surgery. Several small, randomized trials did not demonstrate a significant reduction in major cardiac morbidity and mortality in patients so monitored during aortic surgery. A large-scale cohort study performed by Polanczyk and colleagues in which patients who had pulmonary catheters were matched to those who did not by using a propensity score also failed to demonstrate significant benefit. In fact, they observed an increased incidence of congestive heart failure and untoward noncardiac outcomes in the catheter group. A total of 1994 patients were randomly allocated to goal-directed therapy guided by a pulmonary catheter or to standard care without the use of a pulmonary catheter in patients undergoing urgent or elective major surgery. No difference in survival occurred, but pulmonary embolism developed at a higher rate in the catheter group than in the standard-care group. Current evidence therefore does not support the routine use of pulmonary artery catheterization

for high-risk patients undergoing major noncardiac surgery. Determining whether these results apply to the high-risk vascular surgical population and whether use of a pulmonary artery catheter provides benefit in specific clinical situations will require further work.

TEE represents another means of assessing intraoperative cardiac function. This tool sensitively monitors intraoperative wall motion abnormalities and fluid status. In patients undergoing aortic cross-clamping, TEE showed significantly better sensitivity in detecting intraoperative ischemia than did electrocardiographic monitoring. For noncardiac surgery, a study of TEE, 2-lead electrocardiography, and 12-lead electrocardiography demonstrated minimal additive value of TEE over 2-lead electrocardiography. TEE monitoring may nonetheless prove valuable in guiding treatment in patients with unstable hemodynamics who have uncertain fluid status and/or myocardial function.

Transfusion Threshold

Much controversy surrounds the optimal hemoglobin level at which transfusion is indicated in high-risk noncardiac surgical patients. No randomized trials have evaluated the optimal transfusion threshold, although a great deal of anecdotal evidence exists. Several small cohort studies have shown that hematocrits in the 27% to 29% range represent the point below which the incidence of myocardial ischemia and potentially MI increases. A large-scale trial of transfusion triggers in the ICU did not document increased morbidity and mortality when a hemoglobin concentration lower than 7 g/dL was used as a transfusion threshold, but trends toward increased morbidity emerged in the subset of patients with ischemic heart disease. In the FOCUS (Transfusion Trigger Trial for Functional Outcomes in Cardiovascular Patients Undergoing Surgical Hip Fracture Repair) trial, Carson and colleagues randomly assigned hip fracture patients to a liberal transfusion strategy (a hemoglobin threshold of 10 g/dL) or a restrictive transfusion strategy (symptoms of anemia or at the physician's discretion for a hemoglobin level <8 g/dL).⁵⁰ A liberal transfusion strategy, as compared with a restrictive strategy, did not reduce rates of death or inability to walk independently on 60-day follow-up, nor did it reduce in-hospital morbidity in elderly patients at high cardiovascular risk.

REFERENCES, 1806

The endocrine system is tightly linked with many important cardiovascular diseases. As our understanding of the cellular and molecular effects of various hormones has evolved, we better understand the clinical manifestations that arise from excessive secretion of hormone and from glandular failure and subsequent hormone deficiency states. More than 200 years ago the English physician Caleb Hillier Parry described a woman with goiter and palpitations in whom “each systole shook the whole thorax.” He was the first to suggest a connection between diseases of the heart and enlargement of the thyroid gland. Recognition of the cardiovascular abnormalities associated with pathologic changes in endocrine glands preceded identification of the specific hormones produced by these glands. This chapter reviews the spectrum of cardiac disease states that arise from changes in specific endocrine function. This approach allows us to explore the cellular mechanisms whereby various hormones can alter the cardiovascular system through changes in lipid metabolism and actions on cardiac myocytes, vascular smooth muscle cells, and other target cells and tissues.

PITUITARY GLAND

The pituitary gland consists of two distinct anatomic portions. The anterior pituitary, or adenohypophysis, contains six different cell types; five of them produce polypeptide or glycoprotein hormones, and the sixth is composed of nonsecretory chromophobic cells. Of these cell types, the somatotrophic cells, which secrete human growth hormone (hGH), and the corticotrophic cells, which produce adrenocorticotrophic hormone (ACTH), can contribute to cardiac disease. The posterior pituitary, or neurohypophysis, is the anatomic location

of the nerve terminals that secrete vasopressin (antidiuretic hormone) to control water balance or oxytocin, the milk letdown polypeptide.

Growth Hormone

In adults, excessive secretion of hGH before fusion of the bony epiphysis leads to the clinical syndrome of gigantism, whereas increased secretion of hGH after maturation of the long bones leads to acromegaly. hGH exerts its cellular effects through two major pathways. The first is by binding of the hormone to specific hGH receptors on target cells. Such receptors have been identified in the heart, skeletal muscle, fat, liver, and kidneys, as well as in many additional cell types throughout fetal development.¹ The second growth-promoting effect of hGH results from stimulation of the synthesis of insulin-like growth factor type I (IGF-I). This protein is synthesized primarily in the liver, but other cell types can produce IGF-I under the influence of hGH.

Shortly after identification of the IGF family, it was proposed that this second messenger mediates most actions of hGH. The clinical disease activity of patients with an excess of hGH (acromegaly) correlates better with serum levels of IGF-I than with hGH levels. The ability to promote glucose uptake and cellular protein synthesis gave rise to the term “insulin-like.” IGF-I binds to its cognate IGF-I receptor, which is located on almost all cell types. Genetic experiments have demonstrated that the presence of IGF-I receptors on cell types is closely linked to the ability of these cells to divide. Studies in which the IGF-I receptor was overexpressed in cardiac myocytes reportedly produced an increase in myocyte number and mitotic rate and enhanced the replication of postdifferentiated myocytes. Harnessing of this action could benefit genetic manipulation and, in conjunction with cardiac stem cells, could enhance repair of diseased myocardium.

Infusion of hGH or IGF-I acutely changes hemodynamics. The acute increases in cardiac contractility and cardiac output may result, at least in part, from a decrease in systemic vascular resistance and cardiac afterload.² Short-term administration of hGH and IGF-I does not increase blood pressure.^{3,4}

Cardiovascular Manifestations of Acromegaly

Acromegaly is a relatively uncommon condition (≈900 new cases each year in the United States). Acromegaly and pituitary-dependent human gigantism are associated with markedly increased morbidity and mortality, primarily from cardiovascular disease. Untreated acromegaly, identified by the characteristic clinical signs of acral growth and symptoms and by increased hGH secretion, markedly shortens life expectancy, with less than 20% of patients surviving beyond 60 years. Multiple studies have implicated increased neoplasia arising from the gastrointestinal tract, colon polyps, colon cancer, and pulmonary disease in this increased mortality,⁵ but cardiovascular and cerebrovascular effects, including hypertension, cardiomegaly, congestive heart failure, and cerebral vascular accidents, lead to the major events that limit survival.^{6,7}

The cardiovascular and hemodynamic effects of acromegaly vary considerably depending on age and severity and duration of the disease.⁸ Patients in whom the condition was diagnosed with less than 5 years of disease activity had no significant abnormality in systolic or diastolic blood pressure, but echocardiographic evaluation showed that the left ventricular mass index increased almost 35% and the cardiac index increased 24%.⁹ Measures of systolic function, including stroke index, increased significantly, and systemic vascular resistance rose by 20% in patients with newly diagnosed, untreated acromegaly when compared with age- and sex-matched controls. Left ventricular diastolic function was normal.⁶ These studies contrast with reports that a longer duration of acromegaly produces left ventricular dysfunction and cardiomyopathy. In untreated acromegaly, global left ventricular diastolic dysfunction accompanies cardiac hypertrophy. The regional myocardial systolic strain abnormalities can be identified by Doppler imaging and can be reversed with treatment.¹⁰ A recent study identified impaired diastolic function in acromegaly, especially in older patients with diabetes mellitus.¹¹

Known cardiac disease risk factors—including hypertension, insulin resistance, diabetes mellitus, and hyperlipidemia—frequently occur in patients with acromegaly. Although initial reports suggested that accelerated atherosclerosis causes impairment of cardiac function in patients with longstanding acromegaly, a postmortem study revealed significant coronary artery disease in only 11% of patients dying of disease-related causes. Angiography shows normal or dilated coronary arteries in most cases. Nuclear stress testing is positive in less than 25% of patients, thus indicating that atherosclerosis and ischemic heart disease are unlikely to account for the marked degree of biventricular cardiac hypertrophy, cardiac failure, and cardiovascular mortality. A rather specific functional and histologic change in myocytes appears to arise from the prolonged excessive serum levels of hGH and IGF-I.⁹ As many as two thirds of patients with acromegaly have echocardiographic criteria for left ventricular hypertrophy (LVH).^{6,8} Right ventricular mass also increases in acromegaly, a finding indicating a more generalized process beyond systemic hypertension.¹⁰ Asymmetric septal hypertrophy, initially thought to be common in patients with acromegaly, is an unusual finding. Acromegaly increases the prevalence of aortic and mitral valve disease, which persists despite cure of the acromegaly.¹² Progressive mitral regurgitation and increased left ventricular preload and afterload occur in patients with uncontrolled acromegaly.¹³ Patients with acromegaly may exhibit dilation of the aortic root (aortic ectasia) and/or defects in the cardiac conduction system.^{8,12,14}

Histologic evaluation of acromegalic cardiac tissue reveals an increase in myocyte size (hypertrophy) without an increase in cell number. Acromegaly is associated with interstitial fibrosis and infiltration of a variety of inflammatory cells, including mononuclear cells,

consistent with myocarditis.⁶ Some of these histologic findings might result from IGF-I-promoted programmed cell death (apoptosis).

Functional changes accompany pathologic involvement of the heart in acromegaly.^{9,10} Although approximately 10% of patients with newly diagnosed acromegaly have signs and symptoms of cardiac compromise, this percentage increases markedly with longer disease duration.¹³⁻¹⁵ Some studies have reported a low (4%) incidence of overt left ventricular failure, which suggests that supervening factors, including hypertension, type 2 diabetes, and hyperlipidemia, are necessary to impair contractile function.¹⁶ In acromegaly, LVH and impaired left ventricular function can occur in those with longstanding disease but without hypertension, thus indicating that high levels of hGH and/or IGF-I can produce cardiac myopathic changes *per se*. Overt heart failure is associated with a poor prognosis.¹⁶ Therapy for acromegaly can prevent progression to heart failure.^{17,18}

Abnormalities on the electrocardiogram (ECG), including left-axis deviation, septal Q waves, ST-T wave depression, abnormal QT dispersion, and conduction system defects, develop in up to 50% of patients with acromegaly. A variety of dysrhythmias can occur, including atrial and ventricular ectopic beats, sick sinus syndrome, and supraventricular and ventricular tachycardia.⁶ Fourfold increases in complex ventricular arrhythmias and late potentials are observed on signal-averaged ECGs; they are thought to be predictors of ventricular irritability and were also more common in active acromegaly than in treated patients.¹⁴ In contrast, exercise stress testing with electrocardiographic monitoring did not show inducible rhythm disturbances or evidence of ischemia, thus suggesting that the disturbances in left ventricular rhythm are not related to underlying ischemia. Cardiac autonomic function, as measured by heart rate recovery and variability, was altered in patients with newly diagnosed, untreated acromegaly.¹⁹

Secondary hypertension associated with acromegaly occurs in 20% to 40% of patients.^{5,6,8} Given the overall high prevalence rate of hypertension in the adult population and the insidious onset of acromegaly, determining whether hypertension is secondary or merely coincidental is difficult. Improvement in hypertension with therapy for acromegaly, however, suggests that they are related.¹⁷ Although observational studies of survival in patients with acromegaly initially suggested that hypertension was not an independent risk factor for mortality, a survey of patients dying of the disease found that their mean blood pressure was higher than that in those who survived.⁵ The mechanism underlying hypertension in acromegaly is not clearly understood. Patients with newly diagnosed acromegaly and short-duration disease had systolic and diastolic blood pressure no different from that in age- and sex-matched controls, but the cardiac index was significantly increased. In patients with longstanding acromegaly, arterial intimal thickness is increased, and these vascular changes respond to lowering of hGH levels.²

Administration of growth hormone promotes sodium retention and volume expansion and appears to have a potent antinatriuretic effect independent of any effect on aldosterone.^{3,18} Studies of the renin-angiotensin-aldosterone system have shown failure to inhibit release of renin optimally by volume expansion. Both angiotensin-converting enzyme inhibitors and angiotensin receptor blockers cause a paradoxical increase in blood pressure in patients with acromegaly. The role of hyperinsulinemia in the hypertension associated with acromegaly has been questioned. Increased serum insulin can contribute to urinary sodium retention, impairment of endothelial-dependent vasodilation, decreased nitric oxide production, and increased sympathetic activity.

Diagnosis

In 99% of cases, acromegaly arises from benign adenomas of the anterior pituitary gland.^{5,17} At diagnosis most of these neoplasms are classified as macroadenomas (>10 mm), and patients have historical clinical evidence of having had the disease for longer than 10 years. The diagnosis can be confirmed by demonstrating a serum hGH level higher than 5 ng/dL and a serum IGF-I level higher than 300 mIU/mL, measured 1 hour after a 100-g glucose load. In most patients, fasting hGH levels are higher than 10 ng/mL. Localization

of the tumor can be established by magnetic resonance imaging (MRI) of the pituitary gland. Rarely, growth hormone–releasing hormone can be secreted and cause diffuse hyperplasia of the pituitary. Such changes must prompt consideration of a neoplastic lesion residing in other parts (ectopic) of the endocrine system.

Therapy

Transsphenoidal surgery with resection of the adenoma is the procedure of choice for initial management. If hGH and/or IGF-I levels remain elevated, radiotherapy in older patients or dopamine or somatostatin receptor agonists in younger patients can restore normal serum hGH and IGF-I levels. Octreotide acetate is a pharmacologic analogue of somatostatin that in the vast majority of patients, effectively lowers hGH to less than 5 ng/mL. Primary therapy might involve lowering IGF-I levels and shrinking tumor size in selected cases.^{17,20} The cardiovascular complications of acromegaly, including hypertension, LVH, and left ventricular dysfunction, improve with treatment, and survival is significantly better in patients achieving disease remission.^{7,8,13,20} Pegvisomant, a growth hormone receptor antagonist, can normalize IGF-I levels with long-term therapy and may play a role in somatostatin-resistant patients.¹⁴

Growth Hormone Deficiency

Childhood hGH deficiency is associated with increased body fat, central obesity, and an atherogenic lipid profile, as well as with impaired linear growth. Growth hormone replacement therapy appears to reverse or improve all these abnormalities.²¹

ADRENAL GLAND

Adrenocorticotrophic Hormone and Cortisol

The adrenocorticotrophic cells in the anterior pituitary synthesize a large protein (pro-opiomelanocortin), which is then processed within the corticotrophic cell into a family of smaller proteins that include alpha-melanocyte-stimulating hormone, beta-endorphin, and ACTH. ACTH, in turn, binds to specific cells within the adrenal gland. Anatomically, the adrenal gland consists of two major segments, the cortex and the medulla. The cortex zona glomerulosa produces aldosterone, and the zona fasciculata produces primarily cortisol and some androgenic steroids. The zona reticularis also produces cortisol and androgens. ACTH regulates the synthesis of cortisol in the zona fasciculata and reticularis. The zona glomerulosa shows much less ACTH responsiveness and responds primarily to angiotensin II by increased secretion of aldosterone.

Cushing Disease

Excessive cortisol secretion and its attendant clinical disease states can arise from excessive release of ACTH by the pituitary (Cushing disease) or through the adenomatous or rarely malignant neoplastic process arising in the adrenal gland itself (Cushing syndrome).

Well-characterized conditions of adrenal glucocorticoid and mineralocorticoid excess appear to result from the excessively high levels of (ectopic) ACTH produced by small cell carcinoma of the lung, carcinoid tumors, pancreatic islet cell tumors, medullary thyroid cancer, and other adenocarcinomas and hematologic malignancies.

Cortisol, a member of the glucocorticoid family of steroid hormones, binds to monomeric receptors located within the cytoplasm of many cell types (Fig. 81-1). The unliganded glucocorticoid receptors are bound to heat shock protein complexes. After binding cortisol, the receptors dissociate from these complexes, homodimerize or occasionally heterodimerize, translocate to the nucleus, and function as transcription factors. Several cardiac genes contain glucocorticoid response elements in their promoter regions that confer transcriptional-level glucocorticoid responsiveness.²² Such genes include those that encode voltage-gated potassium channels, as well as protein kinases, which serve to phosphorylate and regulate the voltage-gated sodium channels. This expression may be chamber specific and might play a role in the developing fetal heart. In addition, there are more rapidly acting, nontranscriptional pathways by which cortisol can regulate the activity of voltage-gated potassium channels.

The cardiac effects of glucocorticoid excess in Cushing disease arise from the effects of glucocorticoids on the heart, liver, skeletal muscle, and fat tissue.²²⁻²⁴ Accelerated atherosclerosis can

FIGURE 81-1 Schematic representation of a generalized mechanism of action of the nuclear hormone receptor. The mineralocorticoid receptor (MR) has similar affinities for aldosterone and cortisol. Circulating levels of cortisol are 100 to 1000 times greater than those of aldosterone. In MR-responsive cells, the enzyme 11-beta-hydroxysteroid dehydrogenase metabolizes cortisol to cortisone, thereby allowing aldosterone to bind to the MR. The MR and glucocorticoid receptor (GR) are cytoplasmic receptors that after binding ligand, translocate to the nucleus and bind to glucocorticoid response elements (GREs) in the promoter regions of responsive genes. Triiodothyronine (T_3) is transported into the cell via specific membrane proteins and binds to thyroid hormone receptors (TRs), which are bound to thyroid hormone response elements in the promoter regions of T_3 -responsive genes. HSP = heat shock protein; TATA = TATA box promoter region. (Courtesy Dr. S. Danzi.)

result from abnormal glucose metabolism with hyperglycemia, hyperinsulinemia, and hypertension in most patients, as well as from altered clotting and platelet function.²² The mechanism of cortisol-mediated hypertension is multifactorial. In contrast to aldosterone-induced hypertension, intracranial administration of glucocorticoids lowers blood pressure.²⁵ Thus cortisol-mediated hypertension appears not to result from activation of the mineralocorticoid receptor. In addition, antagonism of the effects of glucocorticoid via its cytosolic receptor can block the cortisol-induced elevations in glucose and insulin levels, but not those related to blood pressure.^{26,27} Interestingly, one study suggested that inhibition of sodium retention is also insufficient to block the cortisol-mediated rise in blood pressure, thus pointing to changes in vascular reactivity, systemic vascular resistance, and nitric oxide-mediated vasodilation as candidates for the hypertensive effect.²²

The rise in serum glucose levels and the development of insulin resistance may activate proinflammatory cytokines such as tumor necrosis factor- α and interleukin-6 (IL-6), which may underlie the accelerated atherosclerosis of insulin resistance found in other endocrine disease states.²⁶ Although it typically acts as an anti-inflammatory hormone, cortisol excess can promote inflammation and accelerate atherosclerosis by producing insulin resistance, changes in corticosteroid binding protein, and regulation of proinflammatory cytokines.²⁸ The centripetal obesity characteristic of glucocorticoid excess resembles that seen in insulin resistance (metabolic) syndromes. The excess androgen production resulting from increased stimulation of the adrenal cortex by ACTH may also accelerate atherosclerosis in both men and women.

The increased cardiovascular morbidity and mortality of Cushing syndrome can be explained largely by cerebrovascular disease, peripheral vascular disease, coronary artery disease with myocardial infarction, and chronic congestive heart failure.^{24,27} Studies of left ventricular structure and function have shown hypertrophy and impaired contractility in 40% of patients.²⁹ Cushing syndrome can be manifested as dilated cardiomyopathy.³⁰ A recent study of 15 patients with Cushing syndrome showed increased coronary artery calcification and plaque volume, as measured by Agatston scores, when compared with age-matched controls.³¹ In addition, the marked muscle weakness resulting from corticosteroid-induced skeletal myopathy contributes to impaired exercise tolerance.

Patients with Cushing disease can exhibit a variety of electrocardiographic changes. The duration of the PR interval appears to correlate inversely with adrenal cortisol production rates.²² The mechanism underlying this correlation may be related to expression or regulation of the voltage-gated sodium channel (SCN5A). Changes on the ECG, specifically in the PR and QT intervals, may also arise from the direct (nongenomic) effects of glucocorticoids on the voltage-gated potassium channel (Kv1.5) in excitable tissues.^{22,24}

A particular complex of cardiac and adrenal lesions, referred to as the Carney complex, combines Cushing syndrome, cardiac myxoma, and a variety of pigmented dermal lesions (not café au lait spots). This monogenic autosomal dominant trait maps to the q2 region of chromosome 17.³² Myxomas most commonly occur in the left atrium but can arise throughout the heart, can develop at young ages, and can be multicentric.

Diagnosis

Diagnosis of Cushing disease and Cushing syndrome requires the demonstration of increased cortisol production as reflected by an elevated 24-hour urinary free cortisol or nocturnal salivary cortisol level.²⁸ ACTH measurements to determine whether the disease is pituitary, adrenal, or ectopically based and anatomic localization of the suspected lesions with MRI confirm the laboratory findings. Except in the setting of childhood asthma or other diseases requiring high-dose corticosteroid therapy, Cushing syndrome is rare in the pediatric population.

Treatment

Treatment of excess cortisol production depends on the underlying mechanisms. In Cushing disease, transsphenoidal hypophysectomy

with or without postoperative radiation therapy can partially or completely reverse the increased ACTH production by the anterior pituitary. Cushing syndrome requires surgical removal of one (adrenal adenoma, adrenal carcinoma) or both (multiple nodular) adrenal glands. In nonsurgical patients, the adrenal enzyme inhibitor ketoconazole can reverse the excessive cortisol production. Immediately after surgery, cortisol and mineralocorticoid (fludrocortisone) must be replaced to prevent adrenal insufficiency. Treatment of the ectopic ACTH syndrome requires identification and treatment of the neoplastic process. Clinical signs and symptoms of Cushing syndrome often develop in patients treated with exogenous steroids at doses equivalent to 20 mg of prednisone daily for more than 1 month. Even mild or subclinical degrees of Cushing syndrome (adrenal incidentaloma) appear to increase the risk for cardiovascular disease.³⁰ In all cases, treatment leading to remission of the hypercortisolism led to amelioration of the cardiac changes.³³

Hyperaldosteronism (See also Chapter 43)

Aldosterone production by the zona glomerulosa is under control of the renin-angiotensin system. Renin secretion responds primarily to changes in intravascular volume. Aldosterone synthesis and secretion are primarily regulated by angiotensin II, which binds to the angiotensin II type I receptor on cells of the zona glomerulosa.³⁴

Aldosterone's mechanism of action on target tissues resembles that reported for glucocorticoids (Fig. 81-1). Aldosterone enters cells and binds to the mineralocorticoid receptor, which then translocates to the nucleus and promotes the expression of aldosterone-responsive genes. In addition to kidney cells, in which mineralocorticoid receptors control sodium transport, *in vitro* studies have demonstrated these receptors in rat cardiac myocytes; they respond to mineralocorticoid stimulation with an increase in protein synthesis. Whether these changes correspond to any relevant *in vivo* cardiac effects is unclear, but aldosterone may augment the development of cardiac hypertrophy and diastolic dysfunction in patients with hypertension.³⁵

The aldosterone antagonists spironolactone and eplerenone compete for receptor binding in the cytosol (Fig. 81-1). In addition to the treatment of primary hyperaldosteronism, recent studies have defined a role for these agents after acute myocardial infarction and for the treatment of left ventricular dysfunction, heart failure, and hypertension (see Chapters 25 and 44).^{36,37}

Although the major cause of increased serum aldosterone levels is related to the physiologic response to activation of the renin-angiotensin system, well-recognized aldosterone-producing benign adrenal adenomas can occur (Conn syndrome). Primary hyperaldosteronism augments sodium retention, causes hypertension, increases renal loss of magnesium and potassium, decreases arterial compliance with a rise in systemic vascular resistance and subsequent vascular damage, and alters sympathetic and parasympathetic neural regulation.³⁸ Many of the changes in the heart and cardiovascular system in hyperaldosteronism result from the associated hypertension.³⁵ Primary aldosteronism may promote atrial fibrillation in patients with hypertension but no structural heart disease. A recent review discussed the approach to the detection, diagnosis, and treatment of patients with primary aldosteronism.³⁹ The genetics of this clinical syndrome and the mechanisms underlying the cardiovascular sequelae, including modulation of the *KCNJ5* gene, remain a focus of study.⁴⁰ The hyperaldosterone-mediated hypokalemia and much of the associated hypertension respond to surgical removal of a unilateral (or occasionally bilateral) benign adrenal adenoma.³⁸

Addison Disease

Long before recognition that the glands situated just above the upper pole of each kidney (suprarenal) synthesize and secrete glucocorticoids and mineralocorticoids, Thomas Addison described the association of atrophy and loss of function of these structures with marked changes in the cardiovascular system. Acute addisonian crisis, one of the most severe endocrine emergencies, is characterized by hypovolemia, hypotension, and acute cardiovascular collapse resulting from renal sodium wasting, hyperkalemia, and loss of vascular tone. Adrenal insufficiency arises most commonly from bilateral loss of

adrenal function on an autoimmune basis; as a result of infection, hemorrhage, or metastatic malignancy; or in selected cases, from inborn errors of steroid hormone metabolism.⁴¹ In contrast, secondary adrenal insufficiency, which results from pituitary-dependent loss of ACTH secretion, leads to a fall in glucocorticoid production, whereas mineralocorticoid production, including aldosterone, remains at relatively normal levels. Studies have addressed the issue of relative hypothalamic-pituitary-adrenal insufficiency in acutely ill patients. Although the actual existence of such an entity and diagnostic criteria for establishing this condition remain to be validated, it has reopened the question of the need for stress-dose cortisol treatment in the management of patients with critical illness.⁴²

Addison disease can occur at any age. In children it may be associated with autoimmune (Hashimoto) thyroid disease. The noncardiac symptoms—including increased pigmentation, abdominal pain with nausea and vomiting, and weight loss—can be chronic, but tachycardia, hypotension, loss of autonomic tone, and electrolyte abnormalities herald impending cardiovascular collapse and crisis.⁴¹ Blood pressure measurements uniformly show low diastolic pressure (<60 mm Hg) along with orthostatic changes that reflect loss of volume and acquired autonomic dysfunction. Laboratory findings in patients with hyponatremia and hyperkalemia indicate loss of aldosterone production (renin levels are high). Hyperkalemia can alter findings on the ECG by producing low-amplitude P waves and peaked T waves. Patients with newly diagnosed, untreated Addison disease have reduced left ventricular, end-systolic, and end-diastolic dimensions in comparison to controls. Cardiac atrophy is an unusual condition; it is seen with malnutrition caused by anorexia, in astronauts after prolonged space flight, in populations with sodium-deficient diets, and characteristically with Addison disease (teardrop heart; **Fig. 81-2**). This atrophy reflects a response to decreases in cardiac workload because restoration of normal plasma volume with mineralocorticoid and glucocorticoid replacement increases ventricular mass.

Diagnosis

Acute adrenal insufficiency characteristically occurs in the setting of acute stress, infection, or trauma in a patient with chronic autoimmune adrenal insufficiency or in children with congenital

abnormalities in cortisol metabolism. It can also develop as a result of bilateral adrenal hemorrhage in patients with severe systemic infection or diffuse intravascular coagulation.⁴¹ Secondary adrenal insufficiency can occur in the setting of hypopituitarism and is usually chronic, but acute changes caused by pituitary hemorrhage (apoplexy) or pituitary inflammation (lymphocytic hypophysitis) can also occur. Acute adrenal insufficiency can develop in patients treated long-term with suppressive doses of corticosteroids (>10 mg of prednisone for more than 1 month) if treatment is stopped precipitously or if an acute severe non-endocrine-related illness arises.

The diagnosis is established when cortisol levels are low (<8 mg/dL) in the morning or during severe stress and fail to rise higher than 20 mg/dL 30 minutes after an intravenous (IV) injection of 0.25 mg of cosyntropin. Diagnosis in the setting of acute illness may be more difficult, and a low (<10 mg/dL) morning serum level of cortisol may suffice to suggest impaired control of secretion.⁴²

Treatment

Management of acute addisonian crisis needs to address three major issues. The first is adequate hydrocortisone replacement—100 mg given as an initial IV bolus, then 100 mg every 8 hours for the first 24 hours, and finally tapering of the dose over the next 72 to 96 hours. The second is restoration of the intravascular fluid deficit with large volumes of normal saline with 5% dextrose. The third is identifying and treating any underlying precipitating cause, including infection, acute cardiac or cerebral ischemia, or intra-abdominal emergency. Long-term treatment consists of oral corticosteroid and mineralocorticoid (fludrocortisone, 0.1 mg/day) replacement, but these patients are at increased risk for all-cause and cardiovascular mortality.⁴³

Prolactin Disease

The most common disorder of the anterior pituitary gland is small (<1.0 cm), prolactin-producing pituitary adenomas causing amenorrhea and galactorrhea. Because prolactin secretion is normally inhibited by hypothalamic dopamine, dopamine agonists such as cabergoline and bromocriptine are first-line treatments. Unlike the experience with Parkinson disease, however, such treatment has not been linked with cardiac valvular disease.⁴⁴

PARATHYROID DISEASE

Diseases of the parathyroid glands can produce cardiovascular disease and alter cardiac function through two mechanisms. The first is changes in the secretion of parathyroid hormone (PTH), a protein hormone that affects the heart, vascular smooth muscle cells, and endothelial cells. The second mechanism is changes in serum calcium levels. Serum ionized calcium regulates the synthesis and secretion of PTH by an exquisitely sensitive negative feedback mechanism.⁴⁵

PTH can bind to its receptor and alter the spontaneous beating rate of neonatal cardiac myocytes through an increase in intracellular cyclic adenosine monophosphate (cAMP). PTH can also alter calcium influx and cardiac contractility in adult cardiac myocytes and relaxation of vascular smooth muscle cells. Moreover, the structurally related PTH-related peptide (PTHrP) is synthesized and secreted in a variety of tissues, including cardiac myocytes. PTHrP can bind to the PTH receptor on cardiac cells and stimulate accumulation of cAMP and contractile activity, as well as regulate L-type calcium currents. Thus the direct effects of increased serum levels of PTHrP on the heart and systemic vasculature can accompany paraneoplastic syndromes characterized by hypercalcemia. Long-term treatment with the recombinant human PTH teriparatide (Fortéo) may require monitoring for adverse cardiac effects.

Hyperparathyroidism

The classic primary hyperparathyroidism producing hypercalcemia most often results from adenomatous enlargement of one of the four

FIGURE 81-2 Routine chest radiograph of a patient with Addison disease related to tuberculosis. In addition to the small cardiac silhouette, calcified lymph nodes are present in the hilum of the right lung. (Courtesy Dr. J.B. Naidich.)

parathyroid glands. Cardiovascular actions of hypercalcemia include an increase in cardiac contractility; shortening of the ventricular action potential duration, primarily through changes in phase 2; and blunting of the T wave and changes in the ST segment, occasionally suggesting cardiac ischemia.⁴⁵ The QT interval is shortened and occasionally accompanied by decreases in the PR interval. Treatment with digitalis glycosides appears to increase sensitivity of the heart to hypercalcemia.

Hypercalcemia may lead to pathologic changes in the heart, including the myocardial interstitium and conducting system, as well as calcific deposits in the valve cusps and annuli. Although initially observed in fairly longstanding and severe hypercalcemia, so-called metastatic calcifications can also occur in secondary parathyroid disease arising from chronic renal failure, in which the serum calcium-phosphorus product constant is exceeded. Left ventricular systolic function is generally maintained in patients with primary hyperparathyroidism, but severe or chronic disease may impair diastolic function. Changes in left ventricular structure and function do not appear to improve by 1 to 2 years after successful parathyroid surgery.^{45,46}

A simultaneous increase in serum immunoreactive PTH (best represented by the intact PTH assay) with elevation of the serum calcium level establishes the diagnosis of primary hyperparathyroidism. Other causes include hypercalcemia of malignancy with an increased level of PTHrP or hypercalcemia arising directly from bony metastases or neoplastic (lymphoma) or non-neoplastic (sarcoidosis) disease leading to an increase in the synthesis and release of 1,25-dihydroxyvitamin D₃. Treatment of hyperparathyroidism is surgical removal of the parathyroid adenoma.⁴⁶

Hypocalcemia

Low serum levels of total and ionized calcium directly alter myocyte function. Hypocalcemia prolongs phase 2 of the action potential duration and the QT interval. Severe hypocalcemia can impair cardiac contractility and gives rise to a diffuse musculoskeletal syndrome consisting of tetany and rhabdomyolysis. Primary hypoparathyroidism is rare and can develop after surgical removal of the parathyroid glands, as may occur after treatment of thyroid cancer, in the setting of polyglandular dysfunction syndromes, as a result of glandular agenesis (DiGeorge) syndrome, and in the rare heritable disorder pseudohypoparathyroidism.

Chronic renal failure is the most common cause of low serum calcium and high PTH levels. In such patients the effects of chronically high levels of PTH (secondary hyperparathyroidism) on the heart and cardiovascular system may both be causative and serve as a biomarker in assessing heart failure treatment strategies.^{47,48} In elderly patients with progression of aortic stenosis, a rise in serum PTH and bone remodeling occurs.⁴⁹ The ability of PTH to stimulate G protein-coupled receptors may impair myocyte contractility and contribute to LVH. Cinacalcet, a recently approved calcimimetic agent, can be used to treat the secondary hyperparathyroidism associated with chronic renal failure. A trial to assess its effectiveness on cardiovascular events, however, showed no significant benefit.⁵⁰

Vitamin D

Observational evidence suggests that lower levels of vitamin D (<30 ng/mL of 25-hydroxyvitamin D) are associated with increased all-cause and cardiovascular morbidity.⁵¹ In postmenopausal women,

increased vitamin D intake reduces their relative risk for the development of cancer. Although low levels of vitamin D occur in patients with chronic renal disease and heart failure, we await the results of ongoing trials to evaluate whether vitamin D supplementation might prevent cardiac disease.⁵²

THYROID GLAND

The thyroid gland and the heart share a close relationship that arises in embryology. In ontogeny, the thyroid and heart anlage migrate together. The close physiologic relationship is affirmed by predictable changes in cardiovascular function across the entire range of thyroid disease states; cardiovascular manifestations are some of the most common and characteristic findings of hyperthyroidism. Diagnosis and management of thyroid hormone-mediated cardiac disease states require understanding of the cellular mechanisms of thyroid hormone on the heart and vascular smooth muscle cells.⁵³

Cellular Mechanisms of Thyroid Hormone Action on the Heart

Under the regulation of thyroid-stimulating hormone (thyrotropin, TSH), the thyroid gland concentrates iodide and, through a series of enzymatic steps, synthesizes predominantly tetraiodothyronine (T₄, 85%) and a smaller percentage of triiodothyronine (T₃, 15%; **Fig. 81-3**). The major source of T₃ synthesis is conversion by 5'-monodeiodination, primarily in the liver, skeletal muscle, and kidneys. Studies have confirmed T₃ as the active form of thyroid hormone that accounts for the vast majority of biologic effects, including stimulation of tissue thermogenesis, alterations in the expression of various cellular proteins, and actions on the heart and vascular smooth muscle cells.^{53,54} Free T₃ enters cells via transport proteins (**Fig. 81-4**) of the MCT and OAT family of cell surface transporters.⁵⁵ Most data indicate that cardiac myocytes cannot metabolize T₄ to T₃. Therefore despite the presence of the relevant enzymes, all the observed nuclear actions and changes in gene expression result from changes in blood levels of T₃. As reported for the steroid and retinoic acid families of receptor proteins, the thyroid hormone receptors bind as homodimers or heterodimers to the thyroid hormone response elements in a promoter

FIGURE 81-3 Schematic representation of thyroid hormone metabolism and the effects of T₃ on the heart and systemic vasculature.

FIGURE 81-4 T_3 enters the cell via specific membrane transporters and binds to nuclear T_3 receptors. The complex binds to thyroid hormone response elements and regulates the transcription of specific genes. Non-nuclear T_3 actions on channels for Na^+ , K^+ , and Ca^{2+} ions are indicated. AC = adenylyl cyclase; β -AR = beta-adrenergic receptor; G_s = guanine nucleotide-binding protein subunit; Kv = voltage-gated potassium channel; mRNA = messenger RNA; NCX = sodium calcium exchanger; PLB = phospholamban; TR = T_3 receptor protein.

Monocarboxylate transporters 8 and 10

region of specific genes. Binding to the promoter regions can activate or repress gene expression.⁵⁶

Thyroid hormone transcriptionally regulates many cardiac proteins (Table 81-1), including structural and regulatory proteins, cardiac membrane ion channels, and cell surface receptors, thus providing a molecular mechanism to explain many of the diverse effects of thyroid hormone on the heart. The first reported and best studied to date are the myosin heavy chain isoforms (alpha and beta). The human ventricle expresses primarily beta-myosin, and limited alterations in isoform expression accompany thyroid disease states. Changes in myosin heavy chain isoform expression occur in the human atria in various diseases, including congestive heart failure,

and whether these changes are mediated by thyroid hormone remains uncertain.^{53,57}

Sarcoplasmic reticulum Ca^{2+} -adenosine triphosphatase (ATPase) (SERCA) is an important ion pump that determines the magnitude of myocyte calcium cycling (see Chapter 21). Reuptake of calcium into the sarcoendoplasmic reticulum early in diastole in part determines the rate at which the left ventricle relaxes (isovolumic relaxation time). The polymeric protein phospholamban regulates the activity of SERCA2; it inhibits SERCA activity in a manner dependent on the level of phosphorylation of the individual phospholamban monomers.⁵⁸ Inotropic agents that enhance cardiac contractility through increases in myocyte cAMP do so by stimulating the phosphorylation of phospholamban. Thyroid hormone inhibits the expression of phospholamban and increases phospholamban phosphorylation.⁵⁷ In genetically engineered animals deficient in phospholamban, cardiac contractility does not increase further after exposure to excess thyroid hormone.⁵⁸ These data indicate that thyroid hormone exerts most of its direct effects on cardiac contractility by regulating cycling of calcium through the SERCA-phospholamban system transcriptionally and post-transcriptionally. This molecular mechanism can explain why diastolic function varies inversely across the entire spectrum of thyroid disease states, including even mild subclinical hypothyroidism (Fig. 81-5),⁵⁹⁻⁶¹ and why even mild degrees of hypothyroidism can contribute to heart failure. In addition, beta-adrenergic blockade of the heart in hyperthyroidism does not decrease the rapid diastolic relaxation, thus further dissociating thyroid hormone from the adrenergic effects of thyrotoxicosis.⁵³

Changes in other myocyte genes, including Na^+ , K^+ -ATPase, account for the increase in basal oxygen consumption of the experimental hyperthyroid heart and explain the decrease in digitalis sensitivity of hyperthyroid patients. Studies have shown that thyroid hormone can also regulate the expression of genes that encode its own nuclear receptors and plasma membrane transport proteins (MCT8 and MCT10) within cardiac myocytes (Table 81-1).

FIGURE 81-5 Diastolic function, as measured by the isovolumic relaxation time, varies over the entire range of thyroid disease, including overt hypothyroidism (OH), subclinical hypothyroidism (SCH), control (C), hyperthyroidism (H), hyperthyroidism after beta-adrenergic blockade (H + P), and hyperthyroidism after treatment to restore normal thyroid function (E).

In addition to the well-characterized nuclear effects of thyroid hormone, some cardiac responses to thyroid hormone appear to be mediated through nongenomic mechanisms,⁶² as suggested by their relatively rapid onset of action—faster than can be accounted for by changes in gene expression and protein synthesis—and failure to be affected by inhibitors of gene transcription. The significance of these diverse actions remains to be established but may explain the ability of acute T_3 treatment to alter cardiovascular hemodynamics.

Thyroid Function Testing

Several sensitive and specific laboratory tests can be performed to establish a diagnosis of thyroid disease with a high degree of precision. The serum TSH level is the most widely used and sensitive measure for the diagnosis of hypothyroidism and hyperthyroidism.⁶³ Serum TSH levels uniformly increase (>3.5 mIU/mL) in patients with primary hypothyroidism, and conversely, because of the normal feedback of excessive levels of T_4 (and T_3) on pituitary synthesis and secretion of TSH, the levels are low in hyperthyroidism (<0.1 mIU/mL). Measures of free T_4 can be useful when coexistent hepatic, nutritional, or genetic disease may alter thyroxine-binding globulin content. Autoimmune thyroid disease (Hashimoto and Graves) can be further diagnosed by using serologic measures of antithyroid antibodies, most specifically antithyroid peroxidase or antithyroglobulin antibodies.

Thyroid Hormone–Catecholamine Interaction

Early observations of the heart in hyperthyroidism emphasized its similarity to that of hyperadrenergic states and, moreover, led to the proposal of enhanced sensitivity to catecholamines in this setting.⁵³ This postulate formed the basis for the test described by Emil Goetsch in 1918, in which hyperthyroidism could be diagnosed by demonstrating a marked cardioacceleration and blood pressure response to small subcutaneous doses of epinephrine. Hyperthyroid subjects have decreased circulating catecholamine concentrations despite the appearance of increased adrenergic signs and symptoms. The increased beta₁-adrenergic receptors on cardiac myocytes observed in experimental hyperthyroidism provide a mechanism for the enhanced catecholamine sensitivity. A carefully controlled study of nonhuman primates, however, found no increase in sensitivity of the heart or cardiovascular system to catecholamines in experimental hyperthyroidism.⁶⁴ Accompanying the increased levels of beta₁-adrenergic receptors and guanosine triphosphate-binding proteins,

TABLE 81-2 Cardiovascular Changes with Thyroid Disease

PARAMETER	NORMAL	HYPERTHYROID	HYPOTHYROID
Systemic vascular resistance (dyne-cm • sec ⁻⁵)	1500-1700	700-1200	2100-2700
Heart rate (beats/min)	72-84	88-130	60-80
Cardiac output (liters/min)	5.8	>7.0	<4.5
Blood volume (% of normal)	100	105.5	84.5

thyroid hormone decreases the expression of cardiac-specific adenylyl cyclase catalytic subunit isoforms (V, VI) and thereby maintains the cellular response to beta-adrenergic agonists and cAMP generation within normal limits.⁵³

Hemodynamic Alterations in Thyroid Disease

Changes in myocardial contractility and hemodynamics occur across the entire spectrum of thyroid disease (Table 81-2; see Fig. 81-5). Multiple studies, including those in experimental animals, as well as invasive and noninvasive measurements in patients, indicate that T_3 regulates cardiac inotropy and chronotropy through direct and indirect mechanisms.⁶⁴⁻⁶⁷ T_3 acts on tissues throughout the body to increase myocardial oxygen consumption and tissue thermogenesis (see Fig. 81-3). Through direct effects on vascular smooth muscle cells, T_3 decreases systemic vascular resistance in arterioles of the peripheral circulation.^{53,57} A decrease in mean arterial pressure and activation of the renin-angiotensin-aldosterone system with increased serum angiotensin-converting enzyme activity occurs, as does an increase in renal sodium reabsorption. The increase in plasma volume, coupled with an increase in erythropoietin, leads to an increase in blood volume and a rise in cardiac preload. Thus a combination of lower systemic vascular resistance (by as much as 50%) and increases in venous return and preload increases cardiac output. Cardiac output may more than double in hyperthyroidism and, conversely, may decrease by as much as 30% to 40% in hypothyroidism. Studies using measurements of acetate metabolism by positron emission tomography (PET) have demonstrated that the marked increase in cardiac output in hyperthyroidism causes no change in energy efficiency.⁶⁸

T_3 appears to reduce systemic vascular resistance by direct effects on vascular smooth muscle cells and through changes in the vascular endothelium that potentially involve the generation of nitric oxide. T_3 can produce vasodilation within hours after administration to patients undergoing coronary artery bypass grafting (CABG) and to patients with chronic congestive heart failure.^{55,67} Arterial compliance also falls in hyperthyroidism, which may explain why mean arterial and diastolic pressure is low and peak systolic pressure increases. Thus the combination of increased cardiac output and decreased arterial compliance, which may be more pronounced in older patients with some degree of arterial vascular disease, leads to systolic hypertension in up to 30% of patients.^{65,66} In hypothyroidism, systemic vascular resistance may increase as much as 30%. Mean arterial pressure rises, with up to 20% of patients having diastolic hypertension. Even mild hypothyroidism may decrease endothelial-derived relaxing factors.⁶⁹ The diastolic hypertension in patients with even mild degrees of hypothyroidism is associated with a low renin level and a decrease in the hepatic synthesis of renin substrate. These alterations lead to a characteristically low level of salt sensitivity, again reinforcing the importance of an increase in systemic vascular resistance underlying the mechanism for diastolic hypertension.

Hyperthyroidism

Cardiovascular symptoms are an integral and often the predominant clinical features of patients with hyperthyroidism.⁵³ Most patients experience palpitations resulting from increases in the rate and force of cardiac contractility. The increase in heart rate is caused by a decrease in parasympathetic stimulation and an increase in sympathetic tone. Heart rates higher than 90 beats/min at rest and during sleep occur commonly, the normal diurnal variation in heart rate is blunted, and the increase during exercise is exaggerated. Many hyperthyroid patients experience exercise intolerance and exertional dyspnea, caused in part by skeletal and respiratory muscle weakness.⁶⁵ In the setting of low vascular resistance and increased preload, cardiac functional reserve is compromised and cannot rise further to accommodate the demands imposed by submaximal or maximal exercise.⁷⁰

A subset of thyrotoxic patients can experience angina-like chest pain. In older patients with known or suspected coronary artery disease, the increase in cardiac work associated with the increase in cardiac output and cardiac contractility in patients with hyperthyroidism can produce myocardial ischemia, which can respond to beta-adrenergic-blocking agents (beta blockers) or restoration of a euthyroid state. Rare patients, usually younger women, experience a syndrome of chest pain at rest associated with ischemic electrocardiographic changes. Cardiac catheterization has demonstrated that most of these patients have angiographically normal coronary arteries, but coronary vasospasm similar to that found in variant angina can occur (see also Chapters 54 and 77). Myocardial infarction develops rarely, and these patients appear to respond to calcium channel-blocking agents or nitroglycerin.⁵³ Recent reports have documented cerebrovascular ischemic symptoms in young, primarily Asian women with Graves disease. This syndrome, moyamoya disease, is characterized by anatomic occlusion of the terminal portions of the internal carotid arteries. Treatment of hyperthyroidism can prevent further cerebral ischemic symptoms, thereby reinforcing the importance of routine thyroid function tests, including TSH, in patients with cardiac or cerebrovascular ischemic symptoms.⁷¹

Hyperthyroidism is associated with a substantial degree of pulmonary hypertension (mean pulmonary artery systolic pressure >50 mm Hg), which is reversible after treatment of Graves disease.⁷² Pulmonary hypertension in turn places a significant degree of stress and afterload on the right ventricle—thus implying that although systemic vascular resistance decreases with thyrotoxicosis, pulmonary vascular resistance does not. Evaluation for thyroid disease by measurement of the serum TSH level may benefit all patients with unexplained pulmonary hypertension.⁶⁵

Atrial Fibrillation (See also Chapter 38)

The most common rhythm disturbance in patients with hyperthyroidism is sinus tachycardia,⁵¹ but atrial fibrillation predominates the clinical impact of hyperthyroidism. The prevalence of atrial fibrillation and the less common forms of supraventricular tachycardia in patients with this disease ranges from 2% to 20%.^{73,74} In contrast to a control population with normal thyroid function and a 2.3% prevalence of atrial fibrillation, the prevalence of atrial fibrillation in those with overt hyperthyroidism was 13.8%. However, in a study of more

than 13,000 hyperthyroid patients, the prevalence of atrial fibrillation was less than 2%, perhaps because of earlier recognition and treatment of hyperthyroidism.⁷³ When that same group of patients was analyzed for age distribution, the prevalence increased stepwise in each decade, with a peak at approximately 15% in patients older than 70 years. In another study, the cumulative incidence of atrial fibrillation in subclinically hyperthyroid patients 60 years or older was 28% over a period of 10 years.⁷⁵ In a study of unselected patients with atrial fibrillation, less than 1% of cases were caused by overt hyperthyroidism. Thus the yield of abnormal thyroid function test results, including a low serum TSH level, appears to be low in patients with new-onset atrial fibrillation. The ability to restore thyrotoxic patients to a euthyroid state and sinus rhythm, however, justifies TSH testing in most patients with a recent onset of otherwise unexplained atrial fibrillation or other supraventricular arrhythmias.^{74,76}

Treatment of atrial fibrillation in the setting of hyperthyroidism includes beta-adrenergic blockade with a beta₁-selective or nonselective agent to control the ventricular response (Table 81-3). This symptomatic measure can be accomplished rapidly, whereas antithyroid treatments leading to restoration of the euthyroid state require more time.⁷⁴ Digitalis may help control the ventricular response in hyperthyroidism-associated atrial fibrillation, but because of the increased rate of digitalis clearance, the decreased sensitivity of drug action resulting from the high cellular levels of Na⁺K⁺-ATPase, and the decreased parasympathetic tone, patients usually require higher doses. Anticoagulation, especially with the new direct thrombin inhibitors, in patients with hyperthyroidism and atrial fibrillation is controversial.⁵³ The potential for systemic or cerebral embolization must be weighed against the risk for bleeding and complications. Whether hyperthyroid patients are at increased risk for systemic embolization per se is not entirely resolved.⁷⁷ In a retrospective study of patients with hyperthyroidism, age rather than atrial fibrillation was the main risk factor for embolization. Retrospective analysis of large series of patients has not demonstrated a prevalence of thromboembolic events greater than the reported risk for major bleeding with warfarin treatment. Thus in younger patients with hyperthyroidism and atrial fibrillation in the absence of other heart disease, hypertension, or other independent risk factors for embolization (CHADS₂ VASc score = 0), the benefits of anticoagulation have not been proved and might be outweighed by the risk.⁵³ Aspirin provides an alternative for lowering the risk for embolic events in younger individuals and can be used safely.

Successful treatment of hyperthyroidism with radioiodine or antithyroid drugs and restoration of normal serum levels of T₄ and T₃ result in reversion to sinus rhythm in two thirds of patients within 2 to 3 months.^{73,74} In older patients or in the setting of atrial fibrillation of longer duration, the rate of reversion to sinus rhythm is lower, and electrical or pharmacologic cardioversion should therefore be attempted, but only after the patient has been rendered euthyroid. Most patients (90%) can be restored to sinus rhythm by electrical cardioversion or pharmacologic measures, and many will remain in sinus rhythm for up to 5 years or more. In a regimen that added disopyramide (300 mg/day) for 3 months after successful cardioversion, patients were more likely to remain in sinus rhythm than were those not so treated.⁷⁶

TABLE 81-3 Beta-Adrenergic Receptor Blockade for the Treatment of Hyperthyroidism*

DRUG	DOSAGE	FREQUENCY	CONSIDERATIONS
Propranolol	10-40 mg	tid or qid	Nonselective β-AR blockade; longest experience
Atenolol	25-100 mg	bid	Relative beta ₁ selectivity; increased patient compliance
Metoprolol	25-50 mg	qid	Relative beta ₁ selectivity
Nadolol	40-160 mg	qd	Nonselective β-AR blockade; once daily; least experience to date
Esmolol	IV pump, 50-100 μg/kg/min		In the ICU setting of severe hyperthyroidism or storm

*Each of these drugs has been approved for the treatment of cardiovascular diseases, but to date none has been approved for the treatment of hyperthyroidism. β-AR = beta-adrenergic receptor; ICU = intensive care unit.

Heart Failure in Thyroid Disease

The cardiovascular alterations in hyperthyroidism include increased resting cardiac output and enhanced cardiac contractility (see [Table 81-2](#)). Nevertheless, a minority of patients have symptoms, including dyspnea on exertion, orthopnea, and paroxysmal nocturnal dyspnea, as well as signs demonstrating peripheral edema, elevated jugular venous pressure, or an S_3 .⁶⁵ This complex of findings, coupled with failure to increase the left ventricular ejection fraction with exercise,⁷⁰ suggests a hyperthyroid cardiomyopathy. The term often used in this setting, *high-output failure*, is not appropriate because although resting cardiac output is as much as two to three times normal, the exercise intolerance does not appear to be a result of cardiac failure but rather a result of skeletal muscle weakness^{51,71} and perhaps associated pulmonary hypertension.⁷² High-output states, however, can increase renal sodium reabsorption and expand plasma volume. Even though systemic vascular resistance falls with hyperthyroidism, the pulmonary vascular bed is not similarly affected, and as a result of the greater output to the pulmonary circulation, pulmonary artery pressure increases.⁶⁵ This leads to a rise in mean venous pressure, jugular venous hypertension, hepatic congestion, and peripheral edema of the type associated with primary pulmonary hypertension or right-sided heart failure.

In patients with longstanding hyperthyroidism and marked sinus tachycardia or atrial fibrillation, low cardiac output, impaired cardiac contractility with a low ejection fraction, an S_3 , and pulmonary congestion can develop—all consistent with heart failure.^{53,57,65} Review of such cases suggests that the impairment in left ventricular function results from the prolonged high heart rate and the development of rate-related heart failure. When the left ventricle becomes dilated, mitral regurgitation may also develop (see [Chapter 63](#)). Recognition of this entity is important because treatment aimed at slowing the heart rate or controlling the ventricular response in atrial fibrillation appears to improve left ventricular function, even before initiation of antithyroid therapy. These patients are critically ill and should be managed in an intensive care unit setting. Some patients with hyperthyroidism, similar to the overall congestive heart failure population, do not tolerate initiation of beta blockers in full doses. Treatment can be started with lower doses of short-acting beta blockers in conjunction with standard forms of treatment of acute heart failure, including diuresis and the use of digitalis.⁶⁵

The increase in the rate-pressure product and oxygen consumption that results from hyperthyroidism can impair cardiac function in older patients with known or suspected ischemic, hypertensive, or valvular heart disease. Prompt recognition of hyperthyroidism in older patients is important because these patients are at higher risk for cardiovascular and cerebral vascular events before⁷⁸ and subsequent to treatment.⁷⁹

Treatment

Treatment of patients with thyrotoxic cardiac disease should include a beta-adrenergic antagonist to lower the heart rate to 10% or 15% above normal. Beta blockers improve the tachycardia-mediated component of ventricular dysfunction, but the direct inotropic effects of thyroid hormone will persist (see [Table 81-3](#) and [Fig. 81-4](#)).⁷⁴ The rapid onset of action and improvement in many of the signs and symptoms of hyperthyroidism indicate that most patients with overt symptoms should receive beta blockers. Definitive therapy can then be accomplished safely with iodine-131 alone or in combination with an antithyroid drug.^{65,74} A recent study affirmed the importance of definitive treatment with iodine-131 by showing that such treatment was associated with lower cardiovascular mortality.⁸⁰

Hypothyroidism

In contrast to the dramatic clinical signs and symptoms of hyperthyroidism, the cardiovascular findings of hypothyroidism are more subtle.⁸¹ Mild degrees of bradycardia, diastolic hypertension, a narrow pulse pressure and relatively quiet precordium, and decreased intensity of the apical impulse are all characteristic. The

hemodynamic changes caused by hypothyroidism diametrically oppose those of hyperthyroidism (see [Table 81-2](#)) and explain many of the physical findings. Despite the decrease in cardiac output and contractility of the hypothyroid myocardium, studies of myocardial metabolism by PET have shown energy inefficiency of the hypothyroid myocardium. The oxygen cost of work increases primarily as a result of the increase in afterload.⁸² Treatment of hypothyroid patients with restoration of a euthyroid state resolves these changes in parallel with return of systemic vascular resistance to lower levels.

Hypothyroidism also produces increases in total and low-density lipoprotein (LDL) cholesterol in proportion to the rise in serum TSH levels.⁸³ Although thyroid hormone can alter cholesterol metabolism through multiple mechanisms, including a decrease in biliary excretion, the primary mechanism involves changes in LDL metabolism caused by decreases in LDL receptor number.⁸⁴ A recent study reported that the liver-selective thyroid hormone agonist eprotirome can cause an additive effect to further lower cholesterol levels in statin-treated patients, which supports this concept.⁸⁵

The serum creatine kinase (CK) level is elevated by 50% to 10-fold in up to 30% of patients with hypothyroidism. Analysis of isoform specificity indicates that more than 96% is CK-MM, consistent with a skeletal muscle origin of the increased enzyme release.⁸⁴ The serum level of CK in patients with hypothyroidism after initiation of standard oral thyroid hormone replacement declines slowly with a half-life of approximately 14 days. Pericardial effusions can occur, in keeping with the observation that patients with hypothyroidism have an increase in the volume of distribution of albumin and a decrease in lymphatic clearance function. Occasionally, the pericardial effusions are large and cause the appearance of cardiomegaly on chest radiographs. Although rare, tamponade with hemodynamic compromise can occur. Echocardiography demonstrates small to moderate effusions in up to 30% of overtly hypothyroid patients; the effusions resolve over a period of weeks to months after initiation of thyroid hormone replacement.⁸¹

As a result of changes in ion channel expression, the ECG in hypothyroidism may show sinus bradycardia, low voltage, and prolongation of the action potential duration and QT interval. The QT prolongation predisposes patients to ventricular arrhythmias, and some patients with acquired torsades de pointes have improved or completely resolved with thyroid hormone replacement.⁵³

Increases in risk factors for atherosclerosis, including hypercholesterolemia, hypertension, and elevated levels of homocysteine, may elevate the risk for atherosclerosis and coronary and systemic vascular disease in patients with hypothyroidism (see [Chapters 42 and 45](#)).^{83,86,87} One study reported increases in abdominal aortic atherosclerosis in older female patients with even mild hypothyroidism.⁸⁶ The possibility that patients with hypothyroidism have an increase in coronary artery disease has clinical importance. One report suggested increased cardiovascular morbidity and mortality with untreated subclinical hypothyroidism,⁸⁷ and another found that the increases in carotid intimal-medial thickness resolve with thyroid hormone replacement.⁸⁸ Noninvasive studies, including nuclear scans, have demonstrated abnormalities in perfusion suggestive of myocardial ischemia, but these defects appear to resolve with thyroid hormone treatment.

In patients younger than 50 years with no history of heart disease, it is generally possible to initiate full replacement doses of levothyroxine (100 to 150 $\mu\text{g/day}$) without concern for untoward cardiac effects. In patients older than 50 years with known or suspected coronary artery disease, the issue is more complicated.⁷⁴

In patients with known coronary artery disease and coexistent hypothyroidism, three major issues need to be addressed. The first is whether to perform coronary artery revascularization before initiating thyroid hormone replacement. If patients are not candidates for percutaneous intervention, CABG can be performed in those with unstable angina, left main coronary artery disease, or three-vessel disease with impaired left ventricular function, even in the setting of overt hypothyroidism. Rarely, a patient has sufficiently profound hypothyroidism to prolong bleeding times and partial thromboplastin times, which requires preoperative supplementation of clotting

factors. Thyroid hormone replacement can be delayed until the post-operative period, when it can be administered in full doses parenterally or orally.^{53,89}

The second issue involves patients with known stable cardiac disease in whom cardiac revascularization is not clinically indicated. Treatment of such patients should begin with low doses (12.5 µg) of levothyroxine and then stepwise increases (12.5 to 25 µg) every 6 to 8 weeks until the serum TSH level normalizes. Thyroid hormone replacement in this setting and its ability to lower systemic vascular resistance and decrease afterload, as well as improve myocardial efficiency, can actually decrease clinical signs of myocardial ischemia. Beta blockers are an ideal concomitant therapy to control the heart rate.

The third important issue involves patients who although potentially at risk for coronary artery disease, exhibit no clinical signs or symptoms. In this group, thyroid hormone replacement can be started at low doses, generally in the range of 25 to 50 µg/day, and then be increased by 25 µg every 6 to 8 weeks until the serum TSH level is normal. If signs or symptoms of ischemic heart disease develop, the same recommendations apply as for patients with known underlying heart disease.

In all patients, thyroid hormone replacement should be sufficient to restore the serum TSH level to normal so that they are clinically euthyroid. The known effects of thyroid hormone on the heart and cardiovascular system do not support the concept that these patients benefit from maintenance of mild hypothyroidism.^{53,82,88} Thyroid hormone replacement should be accomplished with purified preparations of levothyroxine sodium. Preparations containing T₄ and T₃ (thyroid extract) or the existing purified preparations of T₃ do not offer additional benefit. The short half-life of T₃ and the inability to maintain serum levels within the normal range in patients so treated can add to the cardiac risk. An interesting issue is whether some patients with statin-induced myopathy have underlying thyroid disease as a contributing factor. Both conditions have similar myopathy or myalgia symptoms (Table 81-4), and evaluation of these patients should include thyroid function testing with TSH.⁸⁴

Diagnosis

Hashimoto disease, radioiodine therapy for Graves disease, and iodine deficiency (in parts of the world in which it remains a public health problem) are the leading causes of hypothyroidism and produce a diagnostic elevation in serum TSH levels.⁶³ Thus the finding of an elevated TSH level suffices to establish the diagnosis and form the basis for treatment. In routine practice, additional testing with a serum T₄ and T₃ resin uptake assay is confirmatory. The prevalence of hypothyroidism is estimated to be 3% to 4% for overt disease and 7% to 10% for milder forms of disease and increases with advancing age. TSH screening can therefore be advised for all adults, particularly patients with hypertension, hypercholesterolemia, hypertriglyceridemia, coronary or peripheral vascular disease, and unexplained pericardial or pleural effusions, as well as for various musculoskeletal syndromes or statin-associated myopathy.⁸¹

TABLE 81-4 Clinical Characterization of Muscle Disease Syndromes

Hypothyroid Related
Myalgia—nonspecific muscle symptoms, cramping, especially nocturnal; variable CK level
Myopathy—impaired endurance, usually with elevation of the CK level elevation; pseudomyotonia
Hoffmann syndrome—impaired function; pseudohypertrophy; often marked elevations in CK level elevations
Statin Induced
Myopathy—any associated disease
Myalgia—muscle aches, weakness without elevation in the CK level
Myositis—symptoms plus elevated CK level
Rhabdomyolysis—symptoms plus markedly elevated CK levels

Treatment

The response to treatment of hypothyroidism is predictable, especially from a cardiovascular perspective. Stepwise thyroid hormone replacement with levothyroxine sodium (Levoxyl, Synthroid) incrementally decreases serum TSH, serum cholesterol, and serum CK levels and improves left ventricular performance (Fig. 81-6). Full replacement is accomplished when the serum TSH level is normal. In the rare condition of myxedema coma, characterized by the development of hypothermia, altered mental status, hypotension, bradycardia, and hypoventilation in patients with severe and longstanding hypothyroidism, the need for thyroid hormone replacement is more of an emergency, and treatment can be accomplished by intravenous administration of 100 µg of T₄ or 25 to 50 µg of T₃ daily. These patients often require intensive care unit monitoring with volume repletion, gentle warming, and ventilatory support in the presence of CO₂ retention. Administration of hydrocortisone (100 mg three times daily) should be undertaken until the results of serum cortisol testing are obtained. When treated in this manner, hemodynamics, including systemic vascular resistance, cardiac output, and heart rate, improves within 24 to 48 hours.

FIGURE 81-6 Response to stepwise levothyroxine sodium treatment of hypothyroid patients as assessed by serum TSH and T₄ levels and by improvement in left ventricular contractility as measured noninvasively by the change in the pre-ejection period (ΔPEP). (From Crowley WF Jr, Ridgway EC, Bough EW, et al: Noninvasive evaluation of cardiac function in hypothyroidism. Response to gradual thyroxine replacement. *N Engl J Med* 296:1, 1977.)

Subclinical Disease

In contrast to overt symptomatic thyroid disease, subclinical thyroid disease implies the absence of classic hyperthyroid- or hypothyroid-related symptoms in patients with thyroid dysfunction. The definition now includes the demonstration of an abnormal TSH level in patients with normal serum levels of total T_4 , free T_4 , total T_3 , and free T_3 .^{90,91} With the advent of widespread TSH screening, the magnitude of subclinical thyroid disease may exceed that of overt disease by threefold to fourfold.

Subclinical Hypothyroidism

Subclinical hypothyroidism, defined as a TSH level above the upper range of the reference population (usually >3.5 to 4.0 mIU/mL), occurs in up to 9% of unselected populations, and the prevalence increases with advancing age. Although a strong female predilection exists in younger patients, this difference diminishes in older populations. Subclinical hypothyroidism alters lipid metabolism, atherosclerosis, cardiac contractility, and systemic vascular resistance. Cholesterol levels rise in parallel with increments in the elevated TSH level, starting at 5 mIU/liter. A large study of women in Rotterdam has shown that atherosclerosis and myocardial infarction increase with odds ratios of 1.7 and 2.3, respectively, in subclinically hypothyroid women. Of note, the presence of antithyroid antibodies as a measure of autoimmune thyroid disease indicated heightened risk.⁸⁶ Restoration of serum TSH levels to normal after thyroid hormone replacement improves lipid levels, lowers systemic vascular resistance, improves cardiac contractility, and decreases carotid intimal-medial thickness.⁸⁸ Patients with subclinical hypothyroidism have prolonged isovolumic relaxation times, whereas systolic contractile function does not change (Fig. 81-6). Replacement with levothyroxine sodium at a mean dose of 68 μ g/day (range, 50 to 100 μ g/day) restored isovolumic relaxation times to normal, and when compared with the same patients before therapy, systemic vascular resistance declined and systolic function improved significantly.⁹¹ A variety of studies have indicated that the changes in systemic vascular resistance result from alterations in endothelium-dependent vasodilation.⁶⁹ A recent study from the U.K. General Practitioners data base showed that treatment of TSH levels between 5 and 10 mIU/mL lowered the incidence of ischemic heart disease events and cardiovascular mortality in patients younger than 70 years. Taken together, it seems appropriate from a cardiovascular perspective that thyroid hormone replacement be recommended for all patients with subclinical hypothyroidism.⁹² The lack of untoward cardiac effects observed when serum TSH levels normalize indicates that the potential benefits far outweigh the risks associated with treatment.

Subclinical Hyperthyroidism

Subclinical hyperthyroidism is diagnosed when the serum TSH level is low (<0.1 mIU/mL) and T_4 and T_3 levels are normal.⁶¹ A study of atrial fibrillation in patients 60 years or older in the Framingham cohort conclusively established the significance of subclinical hyperthyroidism.⁷⁵ The prevalence of atrial fibrillation after 10 years was 28% in the subclinical hyperthyroid patient population versus 11% in those with normal thyroid function, with a relative risk of 3.1. A large U.S. study of patients 65 years or older confirmed and extended this result. This population-based study of more than 1000 individuals with subclinical hyperthyroidism not receiving levothyroxine therapy or antithyroid medication demonstrated that a TSH level lower than 0.5 mIU/mL is associated with twofold increased mortality, with a relative risk of 2.3 to 3.3 from all causes, largely accounted for by increases in cardiovascular mortality.^{93,94}

Despite the well-established cardiovascular consequences, management of patients with subclinical hyperthyroidism remains controversial.^{74,91} Therapy can be individualized with regard to three specific groups. The first group includes patients receiving thyroid hormone replacement for hypothyroidism in whom the low TSH level is believed to be the result of excessive medication, and reduction of the dose is indicated. The second group includes patients with a previous diagnosis of thyroid cancer who are currently receiving levothyroxine for the express purpose of suppression of TSH. In

younger patients, beta blockers can reverse many (if not all) of the cardiovascular manifestations, including heart rate control, LVH, and atrial ectopy. In older patients, lowering the T_4 dosage can relax the degree of TSH suppression. The third group includes patients in whom subclinical hyperthyroidism results from endogenous thyroid gland overactivity, including Graves disease or nodular goiter. Younger patients in this category appear to have little or no untoward effects,⁹¹ whereas older patients are potentially at risk from atrial fibrillation. In patients older than 60 years, antithyroid therapy (methimazole, 5 to 10 mg/day) can produce improvement, and in patients who respond or require long-term treatment, consideration should be given to the use of radioiodine for definitive therapy.^{53,74}

Amiodarone and Thyroid Function (See Chapter 35)

Amiodarone is an iodine-rich antiarrhythmic agent that is effective for the treatment of ventricular and atrial tachyarrhythmias. Its 30% iodine content by weight and its structural similarity to levothyroxine cause abnormalities in thyroid function test results in as many as 60% of patients treated for short or long periods.⁹⁵ The finding that dronedarone, a recently approved noniodinated benzofuran antiarrhythmic, does not alter thyroid function reinforces this concept.⁹⁶ Similar to other iodinated drugs, amiodarone inhibits the 5'-monodeiodination of T_4 in the liver and pituitary.⁵² Inhibition of T_4 metabolism in the liver decreases serum T_3 and increases serum T_4 levels, whereas serum TSH levels initially remain normal. With more chronic treatment and as the total iodide content in the body rises, T_4 synthesis and release from the thyroid gland can be inhibited, thereby producing a rise in TSH levels. Patients with underlying goiter, autoimmune thyroid disease, or enzymatic defects in thyroid hormone biosynthesis and even some patients without any risk factors can progress to overt chemical and clinical hypothyroidism with a marked rise in serum TSH levels.⁹⁷ The overall prevalence of hypothyroidism in amiodarone-treated patients is between 15% and 30%. Symptoms of hypothyroidism in this setting can be subtle, and significant hypothyroidism can occur even in their absence.⁸¹

Thyroid function should be measured every 3 months in all patients receiving amiodarone (Fig. 81-7). The effect on thyroid function does not depend on the dose and can occur at any time after initiating treatment; furthermore, because of the high lipid solubility and long half-life of amiodarone, this effect can still occur up to 1 year after discontinuing therapy.^{95,97}

Less common but perhaps more challenging is the development of amiodarone-induced thyrotoxicosis. Although not initially observed in the iodine-replete American population, the experience from Italy suggested that it occurs with a prevalence as high as 10%.⁹⁷ The onset was often sudden and could occur shortly after initiation of amiodarone therapy, during chronic treatment, or up to 1 year after stopping therapy. Clinical clues to the development of this condition include a new onset or recurrence of ventricular irritability (increased firing of an implantable cardioverter-defibrillator), decreased warfarin dose requirements, or return or worsening of the obstructive physiology of hypertrophic cardiomyopathy (see Chapter 66). Although the pathogenesis is multifactorial, early studies distinguished two forms of amiodarone-induced thyrotoxicosis. Type I occurs primarily in patients with preexisting thyroid disease and most commonly in iodine-deficient areas. These patients may rarely have an increase in 24-hour radioiodine uptake and frequently some measures of thyroid autoimmunity, including antithyroid antibodies. In contrast, type II disease was identified as a form of thyroiditis presumably mediated by a variety of proinflammatory cytokines, including IL-6. It is primarily a destructive process causing release of preformed thyroid hormone, which may continue for weeks or months and is most often associated with low to absent radioiodine uptake. Further experience has shown that these two types have substantial overlap in many of the distinguishing features. Amiodarone-induced thyrotoxicosis is associated with a threefold increased risk for major adverse cardiovascular events, thus underscoring its clinical importance.⁹⁸ Prompt and effective treatment is indicated.⁹⁵

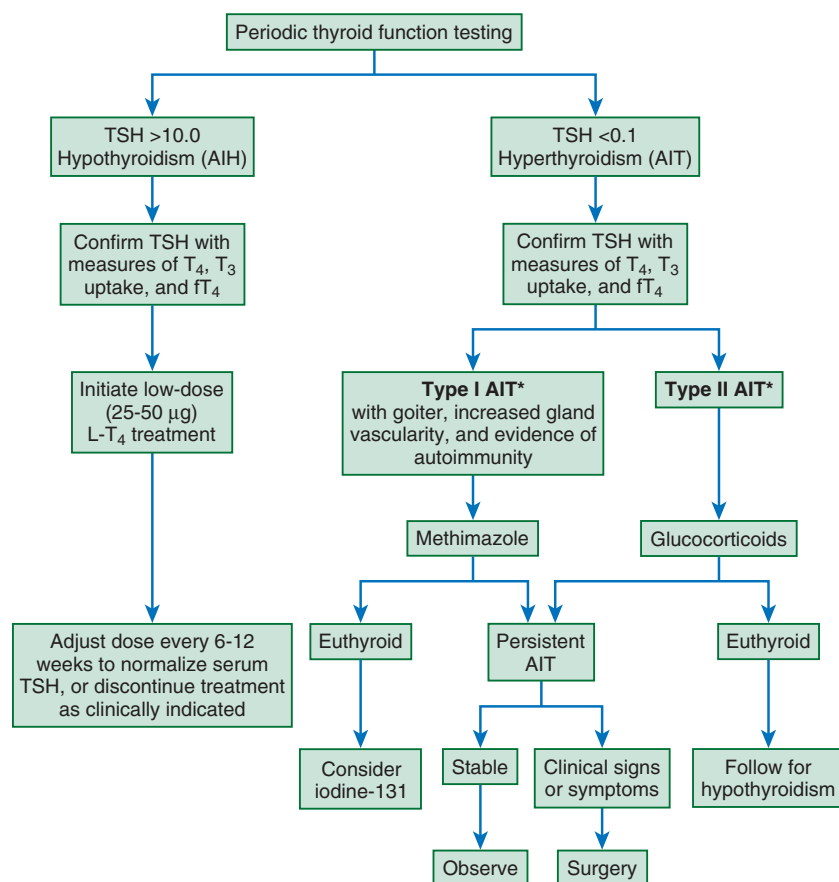

FIGURE 81-7 Amiodarone-induced thyrotoxicosis (AIT) can be diagnosed on the basis of classic signs and symptoms of hypothyroidism or hyperthyroidism or, more commonly, by routine (every 3 to 6 months) thyroid function testing. Any single abnormal TSH level should be confirmed. Clinical hypothyroidism with a TSH level higher than 10 mIU/mL should be treated. AIT management is described and depends on the severity and duration of clinical findings. *Mixed types I and II of AIT may require combination therapy with thionamides and corticosteroids. AIH = amiodarone-induced hypothyroidism; fT₄ = free T₄.

Because of the increased thyroidal and total-body iodine content, use of iodine-131 is almost always ineffective.⁵¹ Similarly, treatment with antithyroid drugs has marginal effectiveness.⁹⁷ Corticosteroids (prednisone, 20 to 40 mg/day) provide benefit, perhaps with increased usefulness in patients with type II disease who have high serum levels of IL-6.⁹⁵ However, corticosteroids can be instituted in all patients because when effective, the response usually occurs within 2 to 4 weeks of initiating treatment. In patients unresponsive to glucocorticoids with evidence of hyperthyroidism—including weight loss, tachycardia, palpitations, worsening angina, ventricular tachycardia, or other untoward cardiac effects—treatment with anti-thyroid therapy (methimazole [Tapazole], 10 to 30 mg/day) is variably effective and can cause considerable side effects. Potassium perchlorate (if available) can have a rapid, but unpredictable effect of lowering thyroid hormone levels and can also cause significant side effects. One earlier small study⁹⁹ and a larger recent report¹⁰⁰ confirmed that total thyroidectomy can be performed safely and can rapidly reverse the hyperthyroidism. Preoperative treatment with beta blockers is indicated, and there have been no reported cases of resulting thyroid storm.

Whether amiodarone-mediated thyroid dysfunction should mandate discontinuation of therapy with the drug is an important issue. There is no evidence that stopping treatment with amiodarone hastens the resolution of chemical hyperthyroidism. Because certain patients require amiodarone therapy to manage arrhythmias and because the duration of drug retention in the body in lipid-soluble stores is in excess of 6 months, it seems prudent to continue amiodarone therapy while making separate management plans to treat the

thyroid dysfunction. Substitution of dronedarone for amiodarone may prevent these untoward effects in those situations in which dronedarone has shown antiarrhythmic efficacy without undue safety concerns (see Chapter 35).⁹⁶

Changes in Thyroid Hormone Metabolism That Accompany Cardiac Disease

In addition to the changes in thyroid function that can result from classic thyroid disease, primary alterations in levels of serum total and free T₃ and occasionally in serum T₄ can accompany a variety of acute and chronic illnesses, including sepsis, starvation, and cardiac disease. In the absence of thyroid gland abnormality, changes in serum T₃ levels result from alterations in thyroid hormone metabolism. Such cases have been referred to as nonthyroidal illness. The mechanism for this decrease in serum T₃ levels is multifactorial and in part related to a decrease in 5'-monodeiodination in the liver.⁵²

A population-based study of patients with cardiac disease has shown that a low serum T₃ level strongly predicts all-cause and cardiovascular mortality.¹⁰¹ Following uncomplicated acute myocardial infarction, serum T₃ levels fall by about 20% and reach a nadir after approximately 96 hours. Experimental myocardial infarction in animals produces a similar decrease in serum T₃ levels, and replacement of T₃ levels to normal may increase left ventricular contractile function.⁵¹ A recent study of T₃ treatment of humans with New York Heart Association (NYHA) class III or IV heart failure has shown similar results.¹⁰²

Children and adults undergoing cardiac surgery with cardiopulmonary bypass demonstrate a predictable fall in serum T₃ levels in the perioperative period.¹⁰³ Although treatment strategies involving acute intravenous administration of T₃ to adults after CABG have shown improvement in cardiac output and a decrease in systemic vascular resistance, overall mortality did not change. In this group of patients, atrial fibrillation decreased by as much as 50% when compared with age-matched controls.¹⁰⁴ Pediatric cardiac patients, especially those undergoing surgery in the neonatal period, demonstrate an even greater decline in serum T₃ levels that can last longer. A low postoperative T₃ level identifies patients at increased risk for morbidity and mortality.¹⁰⁵ A prospective, randomized study has shown that especially in neonates, administration of T₃ in doses sufficient to restore serum T₃ levels to normal decreases the degree of therapeutic intervention and the need for postoperative inotropic agents.¹⁰⁶

In patients with congestive heart failure, the fall in serum T₃ levels correlates with the severity of heart failure as assessed by the NYHA classification.^{57,102} Up to 30% of patients with heart failure have a low serum T₃ level, a finding in patients treated with or without amiodarone. In view of the deleterious effects of hypothyroidism on the myocardium, T₃ replacement may provide benefit. Human studies using a novel form of T₃ that can restore serum T₃ levels to normal and avoid the peaks and valleys of drug levels currently associated with existing drug preparations are needed to answer this question.

PHEOCHROMOCYTOMA

Pheochromocytomas (see Chapters 43 and 89) are primarily benign tumors arising from neuroectodermal chromaffin cells, usually within the adrenal medulla and abdomen, but they may arise anywhere within the plexus of sympathetic adrenergic nerves. Although the prevalence is probably fewer than 1 in 2000 cases of diastolic hypertension, the importance of pheochromocytoma

derives from the dramatic mode in which symptoms can be manifested. Autopsy studies have shown that in 75% of patients the diagnosis was not clinically suspected and that in more than 50% of patients it contributed to mortality.¹⁰⁷

Most pheochromocytomas are 1 cm or larger, the vast majority arise as a unilateral adrenal lesion, and extra-adrenal tumors occur more commonly in children.¹⁰⁸ Although most tumors are sporadic, approximately 10% are familial, and the latter are more often bilateral or occur in an extra-adrenal location. When pheochromocytoma coexists with medullary thyroid carcinoma or occasionally with hyperparathyroidism, it is designated multiple endocrine neoplasia (MEN) syndrome type 2. These patients have a mutation in the RET proto-oncogene. In patients with MEN 2B, pheochromocytomas coexist with medullary thyroid cancer and with mucosal neuromas frequently seen on the lips and tongue. In patients with neurofibromatosis, pheochromocytoma may be present in up to 1%; in von Hippel-Lindau disease, pheochromocytoma develops in association with cerebellar or retinal angiomas and may have specific gene expression, thus indicating a propensity for malignancy.¹⁰⁹

Pheochromocytoma is manifested clinically as headache, palpitations, excessive sweating, tremulousness, chest pain, weight loss, and a variety of other constitutional complaints. Hypertension may be episodic but is usually constant and is paradoxically associated with orthostatic hypotension on arising in the morning. The paroxysmal attacks and classic symptoms result from episodic excessive catecholamine secretion.¹⁰⁷

The first onset of hypertension caused by pheochromocytoma can be at the time of elective surgical intervention for an unrelated condition. As a result of release of norepinephrine with an increase in systemic vascular resistance, cardiac output is minimally (if at all) increased despite increases in the heart rate. The ECG can show LVH, as well as repolarization abnormalities, findings suggesting left ventricular strain. Although ventricular and atrial ectopy and episodes of supraventricular tachycardia can occur, there is little to distinguish the LVH from that of essential hypertension.¹⁰⁷

Impaired left ventricular function and cardiomyopathy have occurred in patients with pheochromocytoma. The mechanism underlying this condition is complex and includes increased left ventricular work and LVH from associated hypertension; potential adverse effects of excess catecholamines on myocyte structure and contractility; and changes in coronary arteries, including thickening of the media, which presumably impairs blood flow to the myocardium. Histologic evidence of myocarditis is present postmortem in patients with previously diagnosed or undiagnosed disease.¹⁰⁷ The possibility of catecholamine-stimulated tachycardia in turn mediating left ventricular dysfunction should be addressed because treatments designed to slow the heart rate may improve left ventricular function.

Release of catecholamines from pheochromocytomas involves diffusion out of chromaffin cells, as well as release of storage vessels, which accounts for the presence of chromogranin A in the circulation. The primary catecholamine released is norepinephrine, but epinephrine can also increase. Demonstration of elevated serum dopamine levels implies malignant transformation, which in turn suggests that the tumor may arise in an extra-adrenal site and have certain gene expression profiles.¹⁰⁹ Rarely, pheochromocytoma can arise within the heart, presumably from chromaffin cells, which are part of the adrenergic autonomic paraganglia.

Diagnosis

An increase in norepinephrine, epinephrine, or its metabolites in serum or blood establishes the diagnosis. Quantitative 24-hour urinary metanephrine levels are the most reliable screening procedures, and plasma catecholamine levels, when determined under proper conditions, are also fairly sensitive.¹⁰⁹ Provocative tests aim to increase plasma catecholamine levels in patients with episodic disease; in contrast, the clonidine suppression test is safe and suppresses plasma norepinephrine levels by more than 50% in patients with essential hypertension, but not in those with pheochromocytoma.¹⁰⁸ Imaging modalities include MRI, which has a high degree of

specificity, and computed tomography, which has a high degree of sensitivity because adrenal lesions are large enough to be detected. Further studies with isotopic precursors of catecholamine biosynthesis, including ¹³¹I-metaiodobenzylguanidine (MIBG), can colocalize catecholamine production with anatomic lesions.

Treatment

Definitive treatment of pheochromocytoma requires removal of the lesion. Accurate preoperative localization reduces operative mortality and eliminates the need for exploratory laparotomy. Endoscopic procedures are now standard. Preoperative pharmacologic management includes 7 to 14 days of alpha-adrenergic blockade, usually with prazosin or phenoxybenzamine. Beta-blocking drug therapy should not be initiated before establishing sufficient alpha blockade. If supraventricular arrhythmias or unremitting tachycardia occurs, beta₁-selective agents such as atenolol are preferred.¹⁰⁹ Operative intervention requires constant blood pressure monitoring, and intravenous phentolamine or sodium nitroprusside may be required to treat episodic hypertension intraoperatively.¹⁰⁷ Postoperative management includes the use of large volumes of crystalloid-containing fluids to maintain blood volume and prevent hypotension. Glucose may be necessary to replace depleted liver glycogen stores. The success of surgery can be determined by effective blood pressure and symptom improvement, as well as by measurement of urinary catecholamines 4 weeks after the procedure. In patients who are not candidates for surgical treatment, metyrosine can decrease catecholamine synthesis and improve most cardiovascular signs and symptoms.

FUTURE PERSPECTIVES

The recognition that a variety of naturally occurring hormones have such profound effects on the heart and cardiovascular system suggests that these actions can be captured to treat a variety of cardiovascular diseases. The ability of thyroid hormone to lower cholesterol levels,⁸⁵ enhance cardiac contractility (especially diastolic function) via novel transcription-based mechanisms, and at the same time lower systemic vascular resistance provides a platform for developing novel therapies. In addition, the recognition that PTH and serum T₃ levels are altered in the setting of various forms of cardiac disease and heart failure can provide new biomarkers for assessing novel treatment strategies.

Hemostasis preserves vascular integrity by balancing the physiologic processes that maintain blood fluidity under normal circumstances and preventing excessive bleeding after vascular injury. Preservation of blood fluidity depends on an intact vascular endothelium and a complex series of regulatory pathways that maintain platelets in a quiescent state and keep the coagulation system in check. In contrast, arrest of bleeding requires rapid formation of hemostatic plugs at sites of vascular injury to prevent exsanguination. Perturbation of hemostasis can lead to thrombosis, which can occur in arteries or veins and causes considerable morbidity and mortality. Arterial thrombosis is the most common cause of acute coronary syndromes, ischemic stroke, and limb gangrene, whereas thrombosis in the deep veins of the leg leads to post syndrome and pulmonary embolism, which can be fatal ([see also Chapter 73](#)).

Most arterial thrombi form on top of disrupted atherosclerotic plaque because plaque rupture exposes thrombogenic material in the plaque core to blood ([see also Chapter 41](#)). This material then triggers platelet aggregation and fibrin formation, which results in the generation of a platelet-rich thrombus that temporarily or permanently occludes blood flow.¹ Transient occlusion of blood flow in coronary arteries may trigger unstable angina, whereas persistent obstruction causes myocardial infarction. The same processes can occur in the cerebral circulation, where temporary arterial occlusion may be manifested as a transient ischemic attack and permanent occlusion can lead to a stroke.

In contrast to arterial thrombi, venous thrombi rarely form at sites of obvious vascular disruption.² Although venous thrombi can develop after surgical trauma to veins or arise secondary to indwelling venous catheters, they usually originate in valve cusps of the deep veins of the calf or in muscular sinuses, where there is stasis. Sluggish blood flow in these veins reduces oxygen supply to the avascular valve cusps. Hypoxemia induces endothelial cells lining the valve cusps to express adhesion molecules, which tether tissue factor-bearing leukocytes and microparticles onto their surface. Tissue factor-bearing leukocytes and microparticles adhere to these activated cells and induce coagulation.³ In addition, webs of DNA released from activated neutrophils, so-called neutrophil extracellular traps (NETs), also contribute to thrombosis by providing a scaffold that binds platelets and promotes their activation and aggregation.⁴ Impaired blood flow exacerbates local thrombus formation by reducing clearance of activated clotting factors. Calf vein thrombi that extend into the proximal veins of the leg can dislodge and travel to the lungs to produce pulmonary embolism.

Arterial and venous thrombi contain platelets and fibrin, but the proportions differ. Arterial thrombi are rich in platelets because of high shear in the injured arteries. In contrast, venous thrombi, which form under low-shear conditions, contain relatively few platelets and consist mostly of fibrin and trapped red cells.² Because of the pre-

dominance of platelets, arterial thrombi appear white, whereas venous thrombi appear red as a result of the trapped red cells.

The antithrombotic drugs used for prevention and treatment of thrombosis target components of thrombi and include antiplatelet drugs, which inhibit platelets; anticoagulants, which attenuate coagulation; and fibrinolytic agents, which induce fibrin degradation ([Fig. 82-1](#)). With the predominance of platelets in arterial thrombi, strategies to inhibit or treat arterial thrombosis focus mainly on antiplatelet agents, although in the acute setting, anticoagulants and fibrinolytic agents may also be used. When arterial thrombi are occlusive and require rapid restoration of blood flow, mechanical and/or pharmacologic methods enable thrombus extraction, compression, or degradation. Although rarely used for this indication, warfarin prevents recurrent ischemic events after acute myocardial infarction. The recent observation that the addition of low-dose rivaroxaban, an oral factor Xa inhibitor, to dual-antiplatelet therapy reduces recurrent ischemic events and stent thrombosis in patients with acute coronary syndrome highlights the potential usefulness of anticoagulants for secondary prevention ([see also Chapters 52 and 53](#)).

Anticoagulants are the mainstay for prevention and treatment of venous thromboembolism (VTE) because venous thrombi contain predominantly fibrin.² Antiplatelet drugs are less effective than anticoagulants for prevention of venous thrombosis because of the limited platelet content of venous thrombi. Nonetheless, when given for secondary prevention, aspirin produces about a 30% reduction in risk for recurrent VTE,^{5,6} a finding that highlights the overlap between venous and arterial thrombosis. Selected patients with VTE benefit from fibrinolytic therapy⁶—for example, patients with massive or submassive pulmonary embolism achieve more rapid restoration of pulmonary blood flow with systemic or catheter-directed fibrinolytic therapy than with anticoagulant therapy alone ([see Chapter 73](#)). Similarly, some patients with extensive deep vein thrombosis in the iliac and/or femoral veins may have a better outcome with catheter-directed fibrinolytic therapy and/or mechanical thrombus extraction in addition to anticoagulants.

Starting with a review of hemostasis and thrombosis that highlights the processes involved in platelet activation and aggregation, blood coagulation, and fibrinolysis, this chapter focuses on antiplatelet, anticoagulant, and fibrinolytic drugs in common use. It also provides a brief overview of new antithrombotic drugs in advanced stages of development.

HEMOSTATIC SYSTEM

The major components of the hemostatic system are the vascular endothelium, platelets, and coagulation and fibrinolytic systems.

FIGURE 82-1 Classification of antithrombotic drugs.

Vascular Endothelium (See Chapter 41)

A monolayer of endothelial cells lines the intimal surface of the circulatory tree and separates blood from the prothrombotic subendothelial components of the vessel wall. Accordingly, the vascular endothelium encompasses about 10^{13} cells and covers a vast surface area. Rather than serving as a static barrier, healthy vascular endothelium is a dynamic organ that actively regulates hemostasis by inhibiting platelets, suppressing coagulation, and promoting fibrinolysis.

Platelet Inhibition

Endothelial cells synthesize prostacyclin and nitric oxide and release them into blood. These agents not only serve as potent vasodilators but also inhibit platelet activation and subsequent aggregation by stimulating adenylate cyclase and increasing intracellular levels of cyclic adenosine monophosphate (cAMP). In addition, endothelial cells express CD39 on their surface. This membrane-associated ecto-adenosine diphosphatase (ecto-ADPase) attenuates platelet activation by degrading ADP.⁷

Anticoagulant Activity

Intact endothelial cells play an essential part in the regulation of thrombin generation. Endothelial cells express heparan sulfate proteoglycans on their surface. Like medicinal heparin, heparan sulfate binds circulating antithrombin and enhances its activity. Heparan sulfate proteoglycans also bind tissue factor pathway inhibitor (TFPI), a naturally occurring inhibitor of coagulation.⁸ Administration of heparin or low-molecular-weight heparin (LMWH) displaces glycosaminoglycan-bound TFPI from the vascular endothelium, and the TFPI released may contribute to the antithrombotic activity of these drugs by inhibiting tissue factor-bound factor VIIa in a factor Xa-dependent fashion.

Endothelial cells are key components of the protein C anticoagulant pathway because they express thrombomodulin and endothelial cell protein C receptor (EPCR) on their surface.⁹ The protein C pathway is initiated when thrombin binds to thrombomodulin. Once bound, the substrate specificity of thrombin is altered such that it no longer acts as a procoagulant but becomes a potent activator of protein C (Fig. 82-2). Activated protein C serves as an anticoagulant by degrading and inactivating activated factor V and factor VIII (factors Va and VIIIa, respectively), key cofactors involved in thrombin generation. The EPCR on the endothelial cell surface enhances this pathway by binding protein C and presenting it to the thrombin-thrombomodulin complex for activation.⁹

Fibrinolytic Activity

The vascular endothelium promotes fibrinolysis by synthesizing and releasing tissue and urokinase plasminogen activator (t-PA and u-PA, respectively), which initiate fibrinolysis by converting plasminogen to plasmin.¹⁰ Endothelial cells in most vascular beds synthesize t-PA constitutively. In contrast, perturbed endothelial cells produce u-PA in the settings of inflammation and wound repair.

Endothelial cells also produce type 1 plasminogen activator inhibitor (PAI-1), the major regulator of both t-PA and u-PA. Therefore net fibrinolytic activity depends on the dynamic balance between release of plasminogen activators and PAI-1. Fibrinolysis is localized to the endothelial cell surface because these cells express annexin II, a coreceptor for plasminogen and t-PA that promotes their interaction. Hence healthy vessels actively resist thrombosis and help maintain platelets in a quiescent state.¹⁰

FIGURE 82-2 Protein C pathway. Activation of coagulation triggers thrombin (IIa) generation. Excess thrombin binds to thrombomodulin (TM) on the endothelial cell surface. Once bound, the substrate specificity of thrombin is altered such that it no longer acts as a procoagulant but becomes a potent activator of protein C (PC). The EPCR binds protein C and presents it to thrombomodulin-bound thrombin for activation. Activated protein C (APC), together with its cofactor protein S (PS), binds to the activated platelet surface and proteolytically degrades factors Va and VIIIa into inactive fragments (Vi and VIIIi). Degradation of these activated cofactors inhibits thrombin generation (double bar).

FIGURE 82-3 Central role of thrombin in thrombogenesis. Vascular injury simultaneously triggers platelet adhesion and activation, as well as activation of the coagulation system. Platelet activation is initiated by exposure of subendothelial collagen and von Willebrand factor (vWF), onto which platelets adhere. Adherent platelets become activated and release ADP and thromboxane A_2 , platelet agonists that activate ambient platelets and recruit them to the site of injury. Coagulation, which is triggered by tissue factor exposed at the site of injury, results in thrombin generation. Thrombin not only converts fibrinogen to fibrin but also serves as a potent platelet agonist. When platelets are activated, glycoprotein (GP) IIb/IIIa on their surface undergoes a conformational change that endows it with the capacity to ligate fibrinogen and mediate platelet aggregation. Fibrin strands then weave the platelet aggregates together to form a platelet/fibrin thrombus.

Platelets

Platelets are anucleate particles released into the circulation after fragmentation of bone marrow megakaryocytes. Because they are anucleate, platelets have limited capacity to synthesize proteins. Thrombopoietin, a glycoprotein synthesized in the liver and kidneys, regulates megakaryocytic proliferation and maturation, as well as platelet production.¹¹ Once they enter the circulation, platelets have a life span of 7 to 10 days.

Damage to the intimal lining of the vessel exposes the underlying subendothelial matrix. Platelets home to sites of vascular disruption and adhere to the exposed matrix proteins. Adherent platelets undergo activation and not only release substances that recruit additional platelets to the site of injury but also promote thrombin generation and subsequent fibrin formation (Fig. 82-3). A potent platelet agonist, thrombin amplifies platelet recruitment and activation. Activated platelets then aggregate to form a plug that seals the leak in the

vasculature. An understanding of the steps in these highly integrated processes helps pinpoint the sites of action of antiplatelet drugs and rationalizes the usefulness of anticoagulants for the treatment of arterial and venous thrombosis.

Adhesion

Platelets adhere to exposed collagen and von Willebrand factor (vWF) and form a monolayer that supports and promotes thrombin generation and subsequent fibrin formation.¹² These events depend on constitutively expressed receptors on the platelet surface, $\alpha_2\beta_1$ and glycoprotein VI (GP VI), which bind collagen, and GP Iba and GP IIb/IIIa ($\alpha_{IIb}\beta_3$), which bind vWF. The platelet surface is crowded with receptors, but those involved in adhesion are the most abundant; every platelet has approximately 80,000 copies of GP IIb/IIIa and 25,000 copies of GP Iba. Receptors cluster in cholesterol-enriched subdomains, which renders them more mobile, thereby increasing the efficiency of platelet adhesion and subsequent activation.¹³

Under low-shear conditions, collagen can capture and activate platelets on its own. The captured platelets undergo cytoskeletal reorganization, which causes them to flatten out and adhere more closely to the damaged vessel wall. Under high-shear conditions, however, collagen and vWF must act in concert to support optimal platelet adhesion and activation. The vWF synthesized by endothelial cells and megakaryocytes assembles into multimers that range from 550 to greater than 10,000 kDa.¹⁴ When released from storage in the Weibel-Palade bodies of endothelial cells or the alpha granules of platelets, most of the vWF enters the circulation, but the vWF released from the abluminal surface of endothelial cells accumulates in the subendothelial matrix, where it binds collagen via its A3 domain. This surface-immobilized vWF can simultaneously bind platelets via its A1 domain. In contrast, circulating vWF does not react with unstimulated platelets. This difference in reactivity probably reflects the conformation of vWF; circulating vWF is in a coiled conformation, which prevents access of its platelet binding domain to vWF receptors on the platelet surface, whereas immobilized vWF assumes an elongated shape, which exposes the A1 domain. In their extended conformation, large vWF multimers act as the molecular glue that tethers platelets to the damaged vessel wall with sufficient strength to withstand higher shear force. Large vWF multimers provide additional binding sites for collagen and heighten platelet adhesion because platelets have more vWF receptors than collagen receptors.¹⁵ Adhesion to collagen or vWF results in platelet activation, the next step in platelet plug formation.

Activation

Adhesion to collagen and vWF initiates signaling pathways that result in platelet activation. These pathways induce cyclooxygenase-1 (COX-1)-dependent synthesis and release of thromboxane A₂ and trigger the release of ADP from storage granules. Thromboxane A₂ is a potent vasoconstrictor and, like ADP, locally activates ambient platelets and recruits them to the site of injury, thereby expanding the platelet plug. To activate platelets, thromboxane A₂ and ADP must bind to their respective receptors on the platelet membrane. The thromboxane receptor (TP) is a G protein-coupled receptor that is found on platelets and the endothelium, which explains why thromboxane A₂ induces vasoconstriction as well as platelet activation.¹⁶ ADP interacts with a family of G protein-coupled receptors on the platelet membrane.^{17,18} The most important of these is P2Y₁₂, which is the target of the thienopyridines and ticagrelor, but P2Y₁ also contributes to ADP-induced platelet activation, and maximal ADP-induced platelet activation requires activation of both receptors. A third ADP receptor, P2X₁, is an adenosine triphosphate (ATP)-gated calcium channel. Platelet storage granules contain ATP, as well as ADP; the ATP released during the platelet activation process may contribute to the platelet recruitment process in a P2X₁-dependent fashion.

Although TP and the various ADP receptors signal through different pathways, they all trigger an increase in the intracellular concentration of calcium in platelets. The increase in calcium induces changes in platelet shape via cytoskeletal rearrangement, granule mobilization and release, and subsequent platelet aggregation.

FIGURE 82-4 Activation of PAR-1 by thrombin. Thrombin (IIa) binds to the amino-terminal of the extracellular domain of PAR-1, where it cleaves a specific peptide bond. Cleavage of this bond generates a new amino-terminal sequence that acts as a tethered ligand and binds to the body of the receptor, thereby activating it. Thrombin then dissociates from the receptor. Analogues of the first five or six amino acids of the tethered ligand sequences, known as thrombin receptor agonist peptides, can independently activate PAR-1. LDPRSFLLR = Leu-Asp-Pro-Arg-Ser-Phe-Leu-Leu-Arg; RLLFS = Arg-Leu-Leu-Phe-Ser.

Activated platelets promote coagulation by expressing phosphatidylserine on their surface, an anionic phospholipid that supports the assembly of coagulation factor complexes. Once assembled, these clotting factor complexes trigger a burst of thrombin generation and subsequent fibrin formation. In addition to converting fibrinogen to fibrin, thrombin amplifies platelet recruitment and activation and promotes expansion of the platelet plug. Thrombin binds to protease-activated receptor types 1 and 4 (PAR-1 and PAR-4, respectively) on the platelet surface and cleaves their extended amino-terminals (Fig. 82-4), thereby generating new amino-terminals that serve as tethered ligands that bind and activate the receptors.¹⁹ Low concentrations of thrombin cleave PAR-1, whereas PAR-4 cleavage requires higher thrombin concentrations. Cleavage of either receptor triggers platelet activation.

In addition to providing a surface on which clotting factors assemble, activated platelets also promote fibrin formation and subsequent stabilization by releasing factor V, factor XI, fibrinogen, and factor XIII. Thus there is coordinated activation of platelets and coagulation, and the fibrin network that results from the action of thrombin helps anchor the platelet aggregates at the site of injury. Activated platelets also release adhesive proteins, such as vWF, thrombospondin, and fibronectin, which may augment platelet adhesion at sites of injury, as well as growth factors such as platelet-derived growth factor (PDGF) and transforming growth factor-beta (TGF- β), which promote wound healing. Platelet aggregation is the final step in formation of the platelet plug.

Aggregation

Platelet aggregation links platelets to each other to form clumps. GP IIb/IIIa mediates these platelet-to-platelet linkages. On nonactivated platelets, GP IIb/IIIa exhibits minimal affinity for its ligands. On platelet activation, GP IIb/IIIa undergoes a conformational change that reflects transmission of inside-out signals from its cytoplasmic domain to its extracellular domain.¹⁸ This transformation enhances the affinity of GP IIb/IIIa for its ligands, fibrinogen, and under high-shear conditions, vWF. Arg-Gly-Asp (RGD) sequences located on fibrinogen and vWF, as well as a platelet-binding Lys-Gly-Asp (KGD) sequence on fibrinogen, mediate their interaction with GP IIb/IIIa. When subjected to high shear, circulating vWF elongates and exposes its platelet binding domain, which enables its interaction with the conformationally activated GP IIb/IIIa.¹⁵ Divalent fibrinogen and multivalent vWF molecules serve as bridges and bind adjacent platelets

together. Once bound to GP IIb/IIIa, fibrinogen and vWF induce outside-inside signals that augment platelet activation and result in the activation of additional GP IIb/IIIa receptors, thus creating a positive feedback loop. Because GP IIb/IIIa acts as the final effector in platelet aggregation, it is a logical target for potent antiplatelet drugs. Fibrin, the ultimate product of the coagulation system, tethers the platelet aggregates together and anchors them to the site of injury.

Coagulation

Coagulation results in the generation of thrombin, which converts soluble fibrinogen to fibrin. Coagulation occurs through the action of discrete enzyme complexes composed of a vitamin K-dependent enzyme and a nonenzyme cofactor that assemble on anionic phospholipid membranes in a calcium-dependent fashion. Each enzyme complex activates a vitamin K-dependent substrate that becomes the enzyme component of the subsequent complex (Fig. 82-5). Together, these complexes generate a small amount of thrombin that feeds back to amplify its own generation by activating the nonenzyme cofactors and platelets. The phosphatidylserine expressed on the surface of activated platelets provides an anionic surface on which the complexes assemble. The three enzyme complexes involved in thrombin generation are extrinsic tenase, intrinsic tenase, and prothrombinase. Although extrinsic tenase initiates the system under most circumstances, the contact system also plays a role in some situations.

Extrinsic Tenase

This complex forms on exposure of tissue factor-expressing cells to blood. Tissue factor exposure occurs after atherosclerotic plaque rupture because the core of the plaque is rich in cells that express tissue factor. Denuding injury to the vessel wall also exposes the tissue factor constitutively expressed by subendothelial fibroblasts and smooth muscle cells. In addition to cells in the vessel wall, circulating monocytes and monocyte-derived microparticles (small membrane fragments) also provide a source of tissue factor.²⁰ When

tissue factor-bearing monocytes or microparticles bind to platelets or other leukocytes and their plasma membranes fuse, transfer of tissue factor takes place. By binding to the adhesion molecules expressed on activated endothelial cells or to P-selectin on activated platelets, these tissue factor-bearing cells or microparticles can initiate or augment coagulation.²¹ This phenomenon probably explains how venous thrombi develop in the absence of obvious vessel wall injury.²

The integral membrane protein tissue factor serves as a receptor for factor VIIa. Blood contains trace amounts of factor VIIa, which has negligible activity in the absence of tissue factor.²² With exposure of tissue factor on anionic cell surfaces, factor VIIa binds in a calcium-dependent fashion to form the extrinsic tenase complex, which is a potent activator of factors IX and X. Once activated, factors IXa and Xa serve as the enzyme components of intrinsic tenase and prothrombinase, respectively.

Intrinsic Tenase

Factor IXa binds to factor VIIIa on anionic cell surfaces to form the intrinsic tenase complex. Factor VIII circulates in blood in a complex with vWF. Thrombin cleaves factor VIII and releases it from vWF, thereby converting it to its activated form. Activated platelets express binding sites for factor VIIIa. Once bound, factor VIIIa binds factor IXa in a calcium-dependent fashion to form the intrinsic tenase complex, which then activates factor X. The change in catalytic efficiency of factor IXa-mediated activation of factor X that occurs with deletion of individual components of the intrinsic tenase complex highlights their importance. Absence of the membrane or factor VIIIa almost completely abolishes enzymatic activity, and the catalytic efficiency of the complete complex is 10^9 -fold greater than that of factor IXa alone. Because intrinsic tenase activates factor X at a rate 50- to 100-fold faster than extrinsic tenase does, intrinsic tenase plays a critical role in the amplification of factor Xa and thrombin generation. The bleeding that occurs in patients with hemophilia—congenital deficiency of factor VIII or factor IX—highlights the importance of intrinsic tenase in hemostasis.

Prothrombinase

Factor Xa binds to factor Va, its activated cofactor, on anionic phospholipid membrane surfaces to form the prothrombinase complex. Activated platelets release factor V from their alpha granules, and this platelet-derived factor V may play a more important role in hemostasis than its plasma counterpart does. Although plasma factor V requires thrombin activation to exert its cofactor activity, the partially activated factor V released from platelets already exhibits substantial cofactor activity. Activated platelets express specific factor Va binding sites on their surface, and bound factor Va serves as a receptor for factor Xa. The catalytic efficiency of activation of prothrombin by factor Xa increases by 10^9 -fold when factor Xa is incorporated into the prothrombinase complex. Prothrombin binds to the prothrombinase complex, where it undergoes conversion to thrombin in a reaction that releases prothrombin fragment 1.2 (F1.2). Plasma levels of F1.2 therefore provide a marker of prothrombin activation.

Fibrin Formation

The final effector in coagulation is thrombin. Thrombin converts soluble fibrinogen to insoluble fibrin. Fibrinogen is a dimeric molecule, each half of which is composed of three polypeptide chains—the α , β , and γ chains. Numerous disulfide bonds covalently link the chains together and join the two halves of the fibrinogen molecule (Fig. 82-6). Electron micrographic studies of fibrinogen reveal a trinodular structure with a central E domain flanked by two D domains. Crystal structures show symmetry of

FIGURE 82-5 Coagulation system. Coagulation occurs through the action of discrete enzyme complexes composed of a vitamin K-dependent enzyme and a nonenzyme cofactor. These complexes assemble on anionic phospholipid membranes in a calcium-dependent fashion. Vascular injury exposes tissue factor (TF), which binds factor VIIa to form extrinsic tenase. Extrinsic tenase activates factors IX and X. Factor IXa binds to factor VIIIa to form intrinsic tenase, which activates factor X. Factor Xa binds to factor Va to form prothrombinase, which converts prothrombin (II) to thrombin (IIa). Thrombin then converts soluble fibrinogen to insoluble fibrin.

FIGURE 82-6 Fibrinogen structure and conversion of fibrinogen to fibrin. A chimeric molecule, each half of fibrinogen is composed of three polypeptide chains—the A α , B β , and γ chains. Numerous disulfide bonds (lines) covalently link the chains together and join the two halves of the fibrinogen molecule to yield a trinodular structure with a central E domain linked via the coiled-coil regions to two lateral D domains. To convert fibrinogen to fibrin, thrombin cleaves specific peptide bonds at the amino (NH₂) terminals of the A α and B β chains of fibrinogen to release fibrinopeptide A (FPA) and fibrinopeptide B (FPB), thereby generating fibrin monomer. Fibrin monomers polymerize to generate protofibrils arranged in a half-staggered overlapping fashion. By covalently cross-linking the α and γ chains of adjacent fibrin monomers, factor XIIIa stabilizes the fibrin network and renders it resistant to degradation.

design with the central E domain, which contains the amino-terminals of the fibrinogen chains joined to the lateral D domains by coiled-coil regions.

Fibrinogen, the most abundant plasma protein involved in coagulation, circulates in an inactive form. Thrombin binds to the amino-terminals of the A α and B β chains of fibrinogen, where it cleaves specific peptide bonds to release fibrinopeptide A and fibrinopeptide B and generates fibrin monomer (Fig. 82-6). Because they are products of the action of thrombin on fibrinogen, plasma levels of these fibrinopeptides provide an index of thrombin activity. Release of fibrinopeptide creates new amino-terminals that extend as knobs from the E domain of one fibrin monomer and insert into preformed holes in the D domains of other fibrin monomers. This creates long strands known as protofibrils that consist of fibrin monomers noncovalently linked together in a half-staggered overlapping fashion.

Noncovalently linked fibrin protofibrils are unstable. By covalently cross-linking the α and γ chains of adjacent fibrin monomers, factor XIIIa stabilizes the fibrin in a calcium-dependent fashion and renders it relatively resistant to degradation. Factor XIII circulates in blood as

a heterodimer consisting of two A and two B subunits. The active site and calcium binding site of factor XIII are localized to the A subunit. Platelets contain large amounts of factor XIII in their cytoplasm, but platelet-derived factor XIII consists only of A subunits. Both plasma factor XIII and platelet factor XIII are activated by thrombin.

Contact Pathway

Current thinking is that exposure of tissue factor represents the sole pathway for activation of coagulation and that the contact system—which includes factor XII, prekallikrein, and high-molecular-weight kininogen—is unimportant for hemostasis because patients deficient in these factors do not have bleeding problems. The physiologic role of factor XI is more difficult to assess because the plasma level of factor XI in patients with congenital deficiency of factor XI, so-called hemophilia C, does not predict the propensity for bleeding. Although the capacity of thrombin to feed back and activate platelet-bound factor XI may explain this phenomenon, platelet-derived factor XI may be more important than circulating factor XI for hemostasis.

We cannot ignore the contact pathway, however, because coronary catheters and other blood-contacting medical devices, such as stents or mechanical valves, probably trigger clotting through this mechanism.²³ Factor XII binds to the surface of catheters or devices, where it undergoes a conformational change that results in its activation. Factor XIIa converts prekallikrein to kallikrein in a reaction accelerated by high-molecular-weight kininogen, and factor XIIa and kallikrein then feed back to activate additional factor XII. Factor XIIa propagates coagulation by activating factor XI (Fig. 82-7).

In addition to its role in device-related thrombosis, the contact pathway may also contribute to the stabilization of arterial and venous thrombi. Thus mice deficient in factor XII or factor XI form small unstable thrombi at sites of arterial or venous damage, thus suggesting that these factors contribute to thrombus stabilization.²⁴ Potential physiologic activators of the contact pathway include polyphosphates released from activated platelets, DNA or RNA released from damaged or apoptotic cells in atherosclerotic plaque, and the DNA and histone network of NETs extruded from activated neutrophils, which not only promotes platelet adhesion and activation but also triggers activation of factor XII. Support for the role of these activators in thrombosis comes from observations in mice that phosphatases and DNA- or RNA-degrading enzymes attenuate thrombosis at sites of injury. The role of these activators in thrombosis in humans is unclear. Although patients with unstable angina have increased plasma levels of factor XIa,²⁵ it is unknown whether this reflects activation by factor XIIa or by thrombin.

Regardless of the extent to which the contact pathway contributes to thrombin generation, the final product of coagulation is fibrin. Hemostasis depends on a dynamic balance between the formation of fibrin and its degradation; the fibrinolytic system mediates fibrin breakdown.

Fibrinolytic System

Fibrinolysis is initiated when plasminogen activators convert plasminogen to plasmin, which then degrades fibrin into soluble fragments (Fig. 82-8). Blood contains two immunologically and functionally distinct plasminogen activators, t-PA and u-PA. t-PA mediates intravascular fibrin degradation, whereas u-PA binds to a specific u-PA receptor (u-PAR) on the surface of cells, where it activates cell-bound plasminogen.¹⁰ Consequently, pericellular proteolysis during

FIGURE 82-7 Contact system. Factor XII is activated by contact with negatively charged surfaces. Factor XIIa converts prekallikrein (PK) to kallikrein (K) and can feed back to activate more factor XII. Similarly, factor XIIa also can feed back to amplify its own generation. Approximately 75% of circulating PK is bound to high-molecular-weight kininogen (HK), which localizes it to anionic surfaces and promotes activation of PK. Factor XIIa propagates clotting by activating factor XI, which then activates factor IX. The resultant factor IXa assembles into the intrinsic tenase complex, which activates factor X to initiate the common pathway of coagulation.

FIGURE 82-8 Fibrinolytic system and its regulation. Plasminogen activators convert plasminogen to plasmin. Plasmin then degrades fibrin into soluble fibrin degradation products. The system is regulated at two levels. PAI-1 regulates the plasminogen activators, whereas alpha₂-antiplasmin serves as the major inhibitor of plasmin.

cell migration and tissue remodeling and repair are the major functions of u-PA.

Regulation of fibrinolysis occurs at two levels. PAI-1 and, to a lesser extent, PAI-2 inhibit the plasminogen activators, whereas alpha₂-antiplasmin inhibits plasmin. Endothelial cells synthesize PAI-1, which inhibits both t-PA and u-PA, whereas monocytes and the placenta synthesize PAI-2, which specifically inhibits u-PA.¹⁰ Thrombin-activated fibrinolysis inhibitor (TAFI) also modulates fibrinolysis and provides a link between fibrinolysis and coagulation.²⁶ Thrombosis can occur if activation of the fibrinolytic system is impaired, whereas excessive activation leads to bleeding. Therefore a review of the mechanisms of action of t-PA, u-PA, and TAFI is worthwhile.

Mechanism of Action of Tissue Plasminogen Activator

t-PA, a serine protease, contains five discrete domains: a fibronectin-like finger domain, an epidermal growth factor domain, two kringle domains, and a protease domain. Synthesized as a single-chain polypeptide, plasmin converts single-chain t-PA into a two-chain form. Both forms of t-PA convert plasminogen to plasmin. Native Glu-plasminogen is a single-chain polypeptide with a Glu residue at its amino-terminal. Plasmin cleavage at the amino-terminal generates Lys-plasminogen, a truncated form with a Lys residue at its new amino-terminal. t-PA cleaves a single peptide bond to convert

single-chain Glu- or Lys-plasminogen into two-chain plasmin, which is composed of a heavy chain containing five kringle domains and a light chain containing the catalytic domain. Because its open conformation exposes the t-PA cleavage site, Lys-plasminogen is a better substrate for t-PA than Glu-plasminogen is, which assumes a circular conformation that renders this bond less accessible.

t-PA has little enzymatic activity in the absence of fibrin, but its activity increases by at least three orders of magnitude when fibrin is present.¹⁰ This increase in activity reflects the capacity of fibrin to serve as a template that binds t-PA and plasminogen and promotes their interaction. t-PA binds to fibrin via its finger and second kringle domains, whereas plasminogen binds fibrin via its kringle domains. Kringle domains are looplike structures that bind Lys residues on fibrin. As fibrin undergoes degradation, more Lys residues are exposed, which provides additional binding sites for t-PA and plasminogen. Consequently, degraded fibrin stimulates activation of plasminogen by t-PA more than intact fibrin does.

Alpha₂-antiplasmin rapidly inhibits circulating plasmin by docking to its first kringle domain and then inhibiting the active site.¹⁰ Because plasmin binds to fibrin via its kringle domains, plasmin generated on the fibrin surface resists inhibition by alpha₂-antiplasmin. This phenomenon endows fibrin-bound plasmin with the capacity to degrade fibrin. Factor XIIIa cross-links small amounts of alpha₂-antiplasmin onto fibrin, which prevents premature fibrinolysis.

Like fibrin, annexin II on endothelial cells binds t-PA and plasminogen and promotes their interaction. Cell surface gangliosides and alpha-enolase may also bind plasminogen and promote its activation by altering its conformation into the more readily activated open form. Plasminogen binds to endothelial cells via its kringle domains. Lipoprotein(a), which also possesses kringle domains, impairs cell-based fibrinolysis by competing with plasminogen for cell surface binding (see also Chapter 45). This phenomenon may explain the association between elevated levels of lipoprotein(a) and atherosclerosis (see also Chapters 42 and 45).²⁷

Mechanism of Action of Urokinase Plasminogen Activator

Synthesized as a single-chain polypeptide, single-chain u-PA (scu-PA) has minimal enzymatic activity. Plasmin readily converts scu-PA into a two-chain form that is enzymatically active and capable of binding u-PA on cell surfaces. Further cleavage at the amino-terminals of two-chain u-PA yields a truncated, lower-molecular-weight form that lacks the u-PA binding domain.¹⁰

Two-chain forms of u-PA readily convert plasminogen to plasmin in the absence or presence of fibrin. In contrast, scu-PA does not activate plasminogen in the absence of fibrin, but it can activate fibrin-bound plasminogen because plasminogen adopts a more open and readily activatable conformation when immobilized on fibrin. Like the higher-molecular-weight form of two-chain u-PA, scu-PA binds to cell surface u-PA, where plasmin can activate it. Many tumor cells elaborate u-PA and express u-PA on their surface. Plasmin generated on these cells endows them with the capacity for metastasis.²⁸

Mechanism of Action of Thrombin-Activated Fibrinolysis Inhibitor

TAFI, a procaryboxypeptidase B-like molecule synthesized in the liver, circulates in blood in a latent form, where thrombin bound to thrombomodulin can activate it. Unless bound to thrombomodulin, thrombin activates TAFI inefficiently.²⁶ Activated TAFI (TAFIa) attenuates fibrinolysis by cleaving Lys residues from the carboxy-terminals of chains of degrading fibrin, thereby removing binding sites for plasminogen, plasmin, and t-PA. TAFI links fibrinolysis to coagulation in that the thrombin-thrombomodulin complex not only activates TAFI, which attenuates fibrinolysis, but also activates protein C, which mutes thrombin generation.

TAFIa has a short half-life in plasma because the enzyme is unstable.²⁶ Genetic polymorphisms can result in the synthesis of more stable forms of TAFIa. Persistent attenuation of fibrinolysis by these variant forms of TAFIa may render patients susceptible to thrombosis.

THROMBOSIS

A physiologic host defense mechanism, hemostasis focuses on arrest of bleeding by forming hemostatic plugs composed of platelets and fibrin at sites of vessel injury. In contrast, thrombosis reflects a pathologic process associated with intravascular thrombi that fill the lumens of arteries or veins.

Arterial Thrombosis (See Chapter 41)

Most arterial thrombi occur on top of disrupted atherosclerotic plaque. Coronary plaque with a thin fibrous cap and a lipid-rich core is most prone to disruption.¹ Rupture of the fibrous cap exposes thrombogenic material in the lipid-rich core to blood and triggers platelet activation and thrombin generation. The extent of plaque disruption and the content of thrombogenic material in the plaque determine the consequences of the event, but host factors also contribute. Breakdown of the regulatory mechanisms that limit platelet activation and inhibit coagulation can augment thrombosis at sites of plaque disruption.

Decreased production of nitric oxide and prostacyclin by diseased endothelial cells can trigger vasoconstriction and platelet activation.²⁹ Proinflammatory cytokines lower expression of thrombomodulin by endothelial cells, which promotes thrombin generation, and stimulate expression of PAI-1, which inhibits fibrinolysis.³⁰

Products of blood coagulation contribute to atherogenesis, as well as to its complications. Microscopic erosions in the vessel wall trigger the formation of tiny platelet-rich thrombi. Activated platelets release PDGF and TGF- β , which promote a fibrotic response.³¹ Thrombin generated at the site of injury not only activates platelets and converts fibrinogen to fibrin but also activates PAR-1 on smooth muscle cells and induces their proliferation, migration, and elaboration of extracellular matrix. Incorporation of microthrombi into plaque promotes their growth, and decreased endothelial cell production of heparan sulfate—which normally limits smooth muscle proliferation—contributes to plaque expansion. The multiple links between atherosclerosis and thrombosis have prompted the term *atherothrombosis*.

Venous Thrombosis (Also see Chapter 73)

Causes of venous thrombosis include those associated with hypercoagulability, which can be genetic or acquired, and the mainly acquired risk factors, such as advanced age, obesity, or cancer, which are associated with immobility (Table 82-1). Inherited hypercoagulable states and these acquired risk factors combine to establish the intrinsic risk for thrombosis in each individual. Superimposed

triggering factors, such as surgery, pregnancy, or hormonal therapy, modify this risk, and thrombosis occurs when the combination of genetic, acquired, and triggering forces exceeds a critical threshold (Fig. 82-9).

Some acquired or triggering factors entail higher risk than do others. For example, major orthopedic surgery, neurosurgery, multiple trauma, and metastatic cancer (particularly adenocarcinoma) are associated with the highest risk, whereas prolonged bed rest, antiphospholipid antibodies, and the puerperium are associated with intermediate risk; pregnancy, obesity, long-distance travel, and the use of oral contraceptives or hormonal replacement therapy are mild risk factors. Up to half of patients with VTE before the age of 45 years have inherited hypercoagulable disorders—so-called thrombophilia—particularly those whose event occurred in the absence of risk factors or with minimal provocation, such as after minor trauma or a long-haul flight or with estrogen use. The following sections describe the inherited and acquired hypercoagulable states.

Inherited Hypercoagulable States

Inherited hypercoagulable states fall into two categories. Some are associated with gain-of-function mutations in procoagulant pathways, such as factor V Leiden, the prothrombin gene mutation, and increased levels of procoagulant proteins; others are associated with loss-of-function mutations of endogenous anticoagulant proteins, such as deficiencies of antithrombin, protein C, and protein S. Although all these inherited hypercoagulable disorders increase the risk for VTE, only increased levels of procoagulant proteins are clearly associated with increased risk for arterial thrombosis.

Factor V Leiden

The factor V Leiden mutation, present in about 5% of white individuals, is the most common inherited thrombophilia. Because of a founder effect, the mutation is less common in Hispanics and blacks and rare in Asians. Caused by a point mutation in the factor V gene, the defect results in the synthesis of a factor V molecule with a Gln residue in place of an Arg residue at position 506—one of three sites where activated protein C cleaves factor Va to inactivate it. Consequently, activated factor V Leiden resists rapid proteolysis and

TABLE 82-1 Classification of Hypercoagulable States

HEREDITARY	MIXED	ACQUIRED
Loss of Function		
Antithrombin deficiency	Hyperhomocysteinemia	Advanced age
Protein C deficiency		Previous venous thromboembolism
Protein S deficiency		Surgery
Gain of Function		
Factor V Leiden		Immobilization
Prothrombin gene mutation		Obesity
		Cancer
Elevated factor VIII, IX, or XI levels		Pregnancy, puerperium
		Drug-induced: L- asparaginase, hormonal therapy

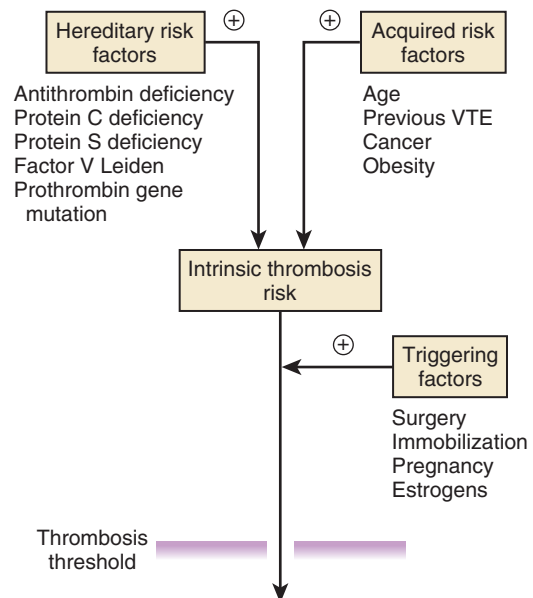

FIGURE 82-9 Thrombosis threshold. Hereditary and acquired risk factors combine to create an intrinsic risk for thrombosis in each individual. This risk is increased by extrinsic triggering factors. If the intrinsic and extrinsic forces exceed a critical threshold at which thrombin generation overwhelms protective mechanisms, thrombosis occurs.

persists 10-fold longer in the presence of activated protein C than its wild-type counterpart does. Inherited in an autosomal dominant fashion, individuals heterozygous for the factor V Leiden mutation have a fivefold increased risk for VTE; those homozygous for the mutation have higher risk. However, the absolute risk for venous thrombosis is low with factor V Leiden, and with a yearly risk of 0.1% to 0.3%, subjects with this disorder have a lifetime risk for thrombosis of only 5% to 10%.

An activated protein C resistance assay establishes the diagnosis of factor V Leiden in most cases. This assay involves calculation of the ratio of the activated partial thromboplastin time (APTT) measured after the addition of activated protein C divided by that determined before its addition. Use of factor V-deficient plasma increases the specificity of the test. If the result of the clotting assay is equivocal, genetic testing using a polymerase chain reaction (PCR)-based assay confirms the diagnosis.

Prothrombin Gene Mutation

The second most common thrombophilic disorder, the prothrombin gene mutation, reflects a G-to-A nucleotide transition at position 20210 in the 3'-untranslated region of the prothrombin gene. This mutation causes elevated levels of prothrombin, which enhances thrombin generation and may limit inactivation of factor Va by activated protein C. The exact mechanism by which the G20210A mutation increases prothrombin levels remains controversial. Enhanced protein synthesis may result from more efficient 3'-end formation, increased messenger RNA stability, enhanced translation efficiency, or some combination of these mechanisms.

The prevalence of the prothrombin gene mutation is about 3% in white persons and lower in Asians and blacks. The mutation increases the risk for venous thrombosis to a similar extent as factor V Leiden does. Laboratory diagnosis depends on genetic screening after PCR amplification of the 3'-untranslated region of the prothrombin gene. Although heterozygotes have 30% higher levels of prothrombin than noncarriers do, the wide range of prothrombin levels in healthy individuals precludes the use of this phenotype for carrier identification.

Elevated Levels of Procoagulant Proteins

Elevated levels of factor VIII and other coagulation factors, including fibrinogen and factors IX and XI, appear to be independent risk factors for venous thrombosis. Increased levels of factor VIII have also been associated with an up to threefold increase in the risk for myocardial infarction.³² Although the molecular bases for the high levels of these coagulation factors have yet to be identified, genetic mechanisms probably contribute because these quantitative abnormalities have high heritability.

Antithrombin Deficiency

Synthesized in the liver, antithrombin regulates coagulation by forming a 1:1 covalent complex with thrombin, factor Xa, or other activated clotting factors. Heparan sulfate or heparin accelerates the rate of antithrombin interaction with its target proteases. Inherited antithrombin deficiency is rare; it occurs in approximately 1 in 2000 people and can be due to decreased synthesis of a normal protein or synthesis of a dysfunctional protein. A parallel reduction in the levels of antithrombin antigen and activity identifies deficiencies caused by decreased synthesis, whereas decreased antithrombin activity in the presence of normal antigen levels identifies dysfunctional forms of antithrombin. A measurement of antithrombin activity with or without added heparin identifies variants with impaired heparin-binding capacity.

Acquired antithrombin deficiency results from decreased synthesis, increased consumption, or enhanced clearance. Decreased synthesis can occur in patients with severe hepatic disease, particularly cirrhosis, or in those given L-asparaginase. Increased activation of coagulation can result in antithrombin consumption in disorders such as extensive thrombosis, disseminated intravascular coagulation, severe sepsis, disseminated malignancy, or prolonged extracorporeal circulation. Heparin treatment can also reduce antithrombin

levels up to 20% by enhancing its clearance. Severe antithrombin deficiency can develop in some patients with nephrotic syndrome because of loss of protein in urine.

Protein C Deficiency

Thrombin initiates the protein C pathway when it binds thrombomodulin on the endothelial cell surface (see Fig. 82-2). Thrombin bound to thrombomodulin activates protein C approximately 1000-fold more efficiently than free thrombin does.⁹ The EPCR augments this process 20-fold by binding protein C and presenting it to the thrombin-thrombomodulin complex for activation.⁹ Activated protein C then dissociates from the activation complex and decreases thrombin generation by inactivating factors Va and VIIIa on the activated platelet surface. For efficient inactivation of these factors, activated protein C must bind to protein S, its cofactor.

Protein C deficiency can be caused by both inherited and acquired forms. Approximately 1 in 200 adults has heterozygous protein C deficiency inherited in an autosomal dominant fashion, but most have no history of thrombosis. The variable phenotypic expression of hereditary protein C deficiency suggests the existence of other, yet unrecognized modifying factors. In contrast to antithrombin deficiency, in which the homozygous state is associated with embryonic lethality, homozygous or doubly heterozygous protein C deficiency can occur. Newborns with these disorders often have purpura fulminans characterized by widespread thrombosis.

Inherited protein C deficiency can result from decreased synthesis of normal protein or from synthesis of dysfunctional forms of protein C. Identification of the type of deficiency requires simultaneous measurement of protein C antigen and activity; reduced synthesis of a normal protein results in a parallel reduction in protein C antigen and activity, whereas synthesis of a dysfunctional protein results in normal antigen with reduced activity.

Acquired protein C deficiency can be due to decreased synthesis or increased consumption. Decreased synthesis can occur in patients with liver disease or in those given warfarin. Protein C consumption can occur with severe sepsis, with disseminated intravascular coagulation, and after surgery. Although antithrombin levels can be low in patients with nephrotic syndrome, protein C levels are normal or elevated in such patients.

Protein S Deficiency

Protein S serves as a cofactor for activated protein C (see Fig. 82-3). In addition, protein S may directly inhibit prothrombin activation because of its capacity to bind factor Va and/or factor Xa, components of the prothrombinase complex. The importance of the direct anticoagulant activity of protein S is uncertain.

In the circulation, approximately 60% of total protein S is bound to C4b-binding protein, a complement component; only the remaining free 40% is functionally active. Diagnosis of protein S deficiency requires measurement of both the free and bound forms of protein S. Inherited protein S deficiency can result from reduced synthesis of the protein or synthesis of a dysfunctional protein. Acquired protein S deficiency can be due to decreased synthesis, increased consumption, loss, or shift of free protein S to the bound form. Decreased synthesis can occur in patients with severe liver disease or in those given warfarin or L-asparaginase. Increased consumption of protein S occurs in patients with acute thrombosis or disseminated intravascular coagulation. Patients with nephrotic syndrome can excrete free protein S in their urine, which causes decreased protein S activity. Total protein S levels in these patients are often normal because the levels of C4b-binding protein increase, thus shifting more protein S to the bound form. C4b-binding protein levels also increase in pregnancy and with the use of oral contraceptives. This shifts more protein S to the bound form and lowers the levels of free protein S and protein S activity. The consequences of this phenomenon are uncertain.

Other Hereditary Disorders

A polymorphism in the gene that encodes the EPCR has been linked to venous thrombosis. Associated with EPCR shedding and high

levels of soluble EPCR, this polymorphism reduces endothelial EPCR, and soluble EPCR competes with its endothelial cell counterpart for protein C binding.³³

A polymorphism in factor XIII that results in more rapid activation by thrombin has been associated with a small reduction in the risk for VTE, myocardial infarction, and ischemic stroke in some case-control studies but not in others.³⁴ The frequency of this polymorphism varies among different ethnic populations, and certain environmental factors, such as obesity and estrogen therapy, may augment its protective effect. More work is needed to determine the extent to which this polymorphism modulates the risk for thrombosis.

Acquired Hypercoagulable States

Such states include surgery and immobilization, advanced age, obesity, cancer, pregnancy and estrogen therapy (oral contraceptive or hormone replacement therapy), a previous history of VTE, antiphospholipid antibody syndrome, and hyperhomocysteinemia (Table 82-1). These conditions can occur in isolation or in conjunction with hereditary hypercoagulable states.

Surgery and Immobilization

Surgery can directly damage veins, and immobilization after surgery leads to stasis in the deep veins of the leg. The risk for VTE in surgical patients depends on the patient's age, the type of surgery, and the presence of active cancer. Patients older than 65 years are at greater risk, and high-risk types of surgery include major orthopedic procedures, neurosurgery, and extensive abdominal or pelvic surgery, especially for cancer. Because the risk for VTE increases up to 20-fold in these patients, they require vigorous thromboprophylaxis until they are fully mobile.

Hospitalization and nursing home confinement account for approximately 60% of cases of VTE, again reflecting the impact of immobilization. Hospitalization for medical illness accounts for a similar proportion of cases as hospitalization for surgery, thus highlighting the need for thromboprophylaxis in medical patients as well as in surgical patients.

Advanced Age

Predominantly a disease of older age, VTE in those younger than 50 years has an incidence of 1 per 10,000 and increases approximately 10-fold per decade thereafter. Men have an overall age-adjusted incidence rate approximately 1.2-fold higher than women do. Although incidence rates are higher in women during the reproductive years, after 45 years of age, men have higher incidence rates. Many potential mechanisms may increase the incidence of VTE with advanced age, including decreased mobility, intercurrent diseases, and vascular endothelium that is less resistant to thrombosis. Levels of procoagulant proteins also increase with age.

Obesity

The risk for VTE increases approximately 1.2-fold for every 10-kg/m² increase in body mass index, but the basis for the association between obesity and VTE is unclear. Obesity leads to immobility; in addition, adipose tissue, particularly visceral fat, expresses proinflammatory cytokines and adipokines, which may promote coagulation by increasing levels of procoagulant proteins or impair fibrinolysis by elevating levels of PAI-1. With the growing epidemic of obesity, the incidence of VTE may increase.

Cancer

Approximately 20% of patients with VTE have cancer.³⁵ Cancer patients in whom VTE develops have reduced survival in comparison to those without VTE. Patients with brain tumors and advanced ovarian or prostate cancer have particularly high rates of VTE. Treatment with chemotherapy, hormonal therapy, and biologic agents (such as erythropoietin and antiangiogenic drugs) further increases the risk, as do central venous catheters and surgery for cancer.

The pathogenesis of thrombosis in cancer patients is multifactorial in origin and represents a complex interplay between the tumor, patient characteristics, and the hemostatic system. Many types of tumor cells express tissue factor or other procoagulants that can initiate coagulation. In addition to its role in coagulation, tissue factor also acts as a signaling molecule that promotes tumor proliferation and spread.³⁶

Patient characteristics that contribute to VTE include immobility and venous stasis secondary to extrinsic compression of major veins by tumor. Surgical procedures, central venous catheters, and chemotherapy can injure vessel walls. In addition, tamoxifen and selective estrogen receptor modulators (SERMs) induce an acquired hypercoagulable state by reducing levels of natural anticoagulant proteins.

A proportion of patients with unprovoked VTE have occult cancer. This observation has prompted some experts to recommend extensive screening for cancer in such patients, but the potential harm—including procedure-related morbidity, the psychological impact of false-positive test results, and the cost of screening—offsets any benefits of this approach. Small studies comparing extensive cancer screening with no screening in patients with unprovoked VTE have not demonstrated a reduction in cancer-related mortality with screening. Therefore unless symptoms suggestive of underlying cancer are present, only age-appropriate screening for breast, cervical, colon, and possibly prostate cancer is indicated because screening for these cancers may reduce mortality.

Pregnancy

Pregnant women have a fivefold to sixfold higher risk for VTE than do age-matched nonpregnant women. VTE occurs in approximately 1 in 1000 pregnancies, and in approximately 1 in 1000 women VTE develops in the postpartum period. VTE is the leading cause of maternal morbidity and mortality. Patient-related factors influence the risk for VTE in pregnancy and the puerperium, including age older than 35 years, body mass index higher than 29, cesarean delivery, thrombophilia, or a personal or family history of VTE. Ovarian hyperstimulation and multiparity are other risk factors.

More than 90% of deep vein thrombi in pregnancy occur in the left leg, probably because the enlarged uterus compresses the left iliac vein by exerting pressure on the overlying right iliac and ovarian arteries. Hypercoagulability occurs in pregnancy because of the combination of venous stasis and changes in blood. Uterine enlargement reduces venous blood flow from the lower extremities. This is not the only mechanism responsible for venous stasis, however, because blood flow from the lower extremities begins to decrease by the end of the first trimester, probably as a result of hormonally induced venous dilation. Systemic factors also contribute to hypercoagulability. Thus levels of procoagulant proteins, such as factor VIII, fibrinogen, and vWF, increase in the third trimester of pregnancy. Coincidentally, suppression of the natural anticoagulant pathways takes place. The net effect of these changes is enhanced thrombin generation, as evidenced by elevated levels of F1.2 and thrombin-antithrombin complexes.

About half the episodes of VTE in pregnancy occur in women with thrombophilia. The risk for VTE in women with thrombophilic defects depends on the type of abnormality and the presence of other risk factors. Risk appears to be highest in women with antithrombin, protein C, or protein S deficiency and lower in those with factor V Leiden or the prothrombin gene mutation. In general, the daily risk for VTE in these women is higher in the postpartum period than it is during pregnancy. The risk during pregnancy is similar in all three trimesters. Therefore women needing thromboprophylaxis require treatment throughout pregnancy and for at least 6 weeks postpartum.

Sex Hormone Therapy (Also see Chapter 77)

Oral contraceptives, estrogen replacement therapy, and SERMs are all associated with an increased risk for venous thrombosis. The relatively high risk for VTE associated with first-generation oral contraceptives prompted the development of low-dose formulations. Currently available low-estrogen combination oral contraceptives

contain 20 to 50 µg of ethinylestradiol and one of several different progestins. Even these low-dose combination contraceptives are associated with a threefold to fourfold increased risk for VTE in comparison to nonusers. In absolute terms this translates to an incidence of 3 to 4 per 10,000 as compared with 5 to 10 per 100,000 in nonusers of reproductive age.

Even though smoking increases the risk for myocardial infarction and stroke in women taking oral contraceptives, it is unclear whether smoking affects the risk for VTE. Obesity, however, affects the risk for both arterial and venous thrombosis. The risk for VTE is highest during the first year of oral contraceptive use and persists only for the duration of use.

Case-control studies suggest a 20- to 30-fold higher risk for VTE in women with inherited thrombophilia who use oral contraceptives than in nonusers with thrombophilia or users without these defects. Despite the increased risk, routine screening for thrombophilia in young women considering oral contraceptive use is not necessary. Based on the incidence and case fatality rate of thrombotic events, estimates suggest that screening 400,000 women would detect 20,000 factor V Leiden carriers and that prevention of a single death would necessitate withholding oral contraceptives in all these women. Even larger numbers of women with less prevalent thrombophilic defects would require screening. Based on these considerations, routine screening is not recommended.

Hormonal replacement therapy with conjugated equine estrogen, with or without a progestin, is associated with a small increase in the risk for myocardial infarction, ischemic stroke, and VTE. SERMs, such as tamoxifen, are estrogen-like compounds that serve as an estrogen antagonist in the breast but as estrogen agonists in other tissues, such as bone and the uterus. Like estrogens, tamoxifen increases the risk for VTE by threefold to fourfold. The risk is higher in postmenopausal women, particularly those receiving systemic combination chemotherapy. Because of this risk, aromatase inhibitors, which antagonize estrogens by blocking their synthesis from androgens, are replacing tamoxifen for the treatment of estrogen receptor–positive breast cancer. These newer agents are associated with a lower risk for VTE than tamoxifen is. Raloxifene, a SERM used to prevent osteoporosis, increases the risk for VTE threefold when compared with placebo, which contraindicates the use of raloxifene for prevention of osteoporosis in women with a history of VTE.

History of Previous Venous Thromboembolism

A history of previous VTE places patients at risk for recurrence. When anticoagulation treatment stops, patients with unprovoked VTE have a risk for recurrence of approximately 10% at 1 year and 30% at 5 years. This risk appears to be independent of whether an underlying thrombophilic defect is present, such as factor V Leiden or the prothrombin gene mutation.

The risk for recurrent VTE is lower in patients whose incident event occurred in association with a transient risk factor, such as major surgery or prolonged immobilization. These patients have a risk for recurrence of approximately 4% at 1 year and 10% at 5 years. Patients whose VTE occurred on the background of minor risk factors, such as oral contraceptive use or a long-haul flight, probably have an intermediate risk for recurrence. Patients at highest risk for recurrence are those with inherited deficiencies of antithrombin, protein C, or protein S; those with antiphospholipid antibody syndrome; patients with advanced malignancy; or those homozygous for factor V Leiden or the prothrombin gene mutation. Their risk for recurrence is likely to be 15% at 1 year and up to 50% at 5 years.

Antiphospholipid Antibody Syndrome

A heterogeneous group of autoantibodies directed against proteins that bind phospholipid, antiphospholipid antibodies can be categorized into those that prolong phospholipid-dependent coagulation assays, so-called lupus anticoagulants (LAs), or anticardiolipin (ACL) antibodies, which target cardiolipin. A subset of ACL antibodies recognizes other phospholipid-bound proteins, particularly beta₂-glycoprotein I.

Patients with thrombosis in association with a persistent LA and/or ACL antibody have antiphospholipid syndrome. Primary antiphospholipid syndrome occurs in isolation, whereas secondary forms are associated with autoimmune disorders, such as systemic lupus erythematosus or other connective tissue diseases. Thrombosis in these patients can be arterial, venous, or placental. Arterial thrombosis can be manifested as a transient ischemic attack, stroke, or myocardial infarction. In addition to deep vein thrombosis and pulmonary embolism, sagittal sinus thrombosis can also occur. Placental thrombosis is probably the root cause of the pregnancy-related complications that characterize antiphospholipid syndrome. Such complications include fetal loss before 10 weeks' gestation and unexplained fetal death after 10 weeks' gestation. Intrauterine growth retardation, pre-eclampsia, and eclampsia can also occur. Treatment with aspirin and/or LMWH during pregnancy may reduce the risk for these complications in women with documented thrombophilic defects.

Laboratory diagnosis of antiphospholipid syndrome requires the presence of an LA or ACL antibody on tests taken at least 6 weeks apart. Diagnosis of an LA requires a battery of phospholipid-dependent clotting tests, whereas immunoassays detect ACL antibodies. Only antibodies of medium to high titer and of the IgG or IgM subclass are associated with thrombosis. Approximately 3% to 10% of healthy individuals have ACL antibodies. Such antibodies also occur with certain infections, such as mycobacterial pneumonia, malaria, or parasitic disorders, and after exposure to some medications. Frequently, these antibodies are of low titer and are transient. Approximately 30% to 50% of patients with systemic lupus erythematosus or other connective tissue disorders have ACL antibodies, and 10% to 20% have an LA.

The mechanism by which antiphospholipid antibodies trigger thrombosis is unclear. These antibodies directly activate endothelial cells in culture and induce the expression of adhesion molecules that can tether tissue factor–bearing leukocytes or microparticles onto their surface. ACL antibodies also interfere with the protein C pathway, inhibit catalysis of antithrombin by endothelial heparan sulfate, and impair fibrinolysis. The importance of these mechanisms in humans remains unclear.

Hyperhomocysteinemia (See Also Chapter 42)

Homocysteine is an intermediate sulfur-containing amino acid that serves as a methyl group donor during the metabolism of methionine, an essential amino acid derived from the diet. The interconversion of methionine and homocysteine depends on the availability of 5-methyltetrahydrofolate, a methyl group donor; vitamin B₁₂ and folate, cofactors in the interconversion; and the enzyme methionine synthase. Increased levels of homocysteine can result from increased production or reduced metabolism. Severe hyperhomocysteinemia and cystinuria, which are rare, usually result from deficiency of cystathionine in beta-synthetase. Mild to moderate hyperhomocysteinemia is more common and is often the result of genetic mutations in methyltetrahydrofolate reductase (MTHFR) in association with nutritional deficiency of folate, vitamin B₁₂, or vitamin B₆. The common C677T and A1298C polymorphisms in MTHFR are associated with reduced enzymatic activity and increased thermolability, respectively, thereby increasing the requirement for nutritional cofactors. Hyperhomocysteinemia can also be associated with certain drugs, such as methotrexate, theophylline, cyclosporine, and most anticonvulsants, as well as with some chronic diseases, such as end-stage renal disease, severe hepatic dysfunction, and hypothyroidism.

A fasting serum homocysteine level higher than 15 mmol/L is considered elevated. Although elevated levels once were a common finding, routine fortification of flour in North America with folic acid has resulted in lower homocysteine levels in the general population. Elevated serum levels of homocysteine may be associated with increased risk for myocardial infarction, stroke, and peripheral arterial disease, as well as VTE.

Administration of folate along with vitamin B₁₂ and vitamin B₆ reduces levels of homocysteine. Nonetheless, randomized trials have shown that such therapy does not lower the risk for recurrent cardiovascular events in patients with coronary artery disease or stroke, nor

does it lower the risk for recurrent VTE. Based on these negative trials and the declining incidence of hyperhomocysteinemia, enthusiasm for screening for hyperhomocysteinemia has declined.

TREATMENT OF THROMBOSIS

Antiplatelet Drugs

The commonly used antiplatelet drugs include aspirin, thienopyridines (ticlopidine, clopidogrel and prasugrel), ticagrelor, dipyridamole, and GP IIb/IIIa antagonists, with distinct sites of action (Fig. 82-9).

Aspirin

The most widely used antiplatelet agent worldwide is aspirin. Because it is an inexpensive and effective drug, aspirin serves as the foundation of most antiplatelet strategies.

Mechanism of Action

Aspirin produces its antithrombotic effect by irreversibly acetylating and inhibiting platelet COX-1 (Fig. 82-10), a critical enzyme in the biosynthesis of thromboxane A_2 . At high doses (≈ 1 g/day), aspirin also inhibits COX-2, an inducible COX isoform found in endothelial cells and inflammatory cells.³⁷ In endothelial cells, COX-2 initiates the synthesis of prostacyclin, a potent vasodilator and inhibitor of platelet activation that antagonizes the effects of thromboxane A_2 .

Indications

Aspirin is widely used for secondary prevention in patients with established coronary, cerebrovascular, or peripheral arterial disease.

In such patients, aspirin produces a 25% reduction in the risk for cardiovascular death, myocardial infarction, or stroke.³⁷ Use of aspirin for primary prevention is more controversial. Meta-analyses suggest that daily aspirin use produces a 25% reduction in the risk for a first cardiovascular event in patients at moderate to high risk for cardiovascular disease. Recent studies, however, have questioned whether the benefits of daily aspirin for primary cardiac protection outweigh its associated risks for gastrointestinal and intracerebral hemorrhage.³⁸ Consequently, aspirin is no longer recommended for primary cardiac prevention unless the baseline cardiovascular risk is at least 1% per year and 10% at 10 years (see also Chapters 42 and 77).

Dosages

Usually administered at dosages of 75 to 325 mg once daily, there is no evidence that higher-dose aspirin is more effective than lower doses, and some meta-analyses suggest reduced efficacy with higher doses.³⁷ Because the side effects of aspirin, particularly gastrointestinal bleeding, are dose dependent, daily aspirin doses of 75 to 150 mg are recommended for most indications. When rapid platelet inhibition is required, an initial dose of aspirin of at least 160 mg should be used.³⁷

Side Effects

The most common side effects are gastrointestinal and range from dyspepsia to erosive gastritis or peptic ulcers with bleeding and perforation.³⁷ Use of enteric-coated or buffered aspirin in place of plain aspirin does not eliminate the risk for gastrointestinal side effects. The risk for major bleeding with aspirin is 1% to 3% per year. With concomitant use of aspirin and anticoagulants such as warfarin, the risk for bleeding increases. When combined with warfarin, use of low-dose aspirin (75 to 100 mg daily) is best. Eradication of *Helicobacter pylori* infection and administration of proton pump inhibitors may reduce the risk for aspirin-induced upper gastrointestinal bleeding in patients with peptic ulcer disease.

Patients with a history of aspirin allergy characterized by bronchospasm should not receive aspirin. This problem occurs in approximately 0.3% of the general population but is more common in patients with chronic urticaria or asthma, particularly those with coexisting nasal polyps or chronic rhinitis.³⁹ Aspirin overdose is associated with hepatic and renal toxicity.

Aspirin Resistance

The term *aspirin resistance* is used to describe both clinical and laboratory phenomena.⁴⁰ A diagnosis of clinical aspirin resistance, defined as failure of aspirin to protect patients from ischemic vascular events, can be made only after such an event occurs. This retrospective diagnosis provides no opportunity to modify therapy. Furthermore, it is unrealistic to expect aspirin, which selectively blocks thromboxane A_2 -induced platelet activation, to prevent all vascular events. The biochemical definition of aspirin resistance involves failure of the drug to inhibit thromboxane A_2 synthesis and/or arachidonic acid-induced platelet aggregation. Potential mechanisms for aspirin resistance include poor adherence, reduced or delayed absorption of aspirin as a consequence of its enteric coating,⁴¹ thromboxane A_2 generation via pathways distinct from COX-1, increased activity of thromboxane A_2 -independent pathways of platelet activation, use of concomitant medications that interfere with the action of aspirin, and pharmacogenetic factors. Tests used for the diagnosis of biochemical aspirin resistance include measurements of thromboxane B_2 , the stable metabolite of thromboxane A_2 , in serum or in urine, and assessment of arachidonic acid-induced platelet aggregation. These tests have not been standardized, however, and there is no evidence that they identify patients at risk for recurrent vascular events or that resistance can be reversed either by giving higher doses of aspirin or by adding other antiplatelet drugs. Until such information is available, testing for aspirin resistance remains a research tool.

Thienopyridines (See Also Chapters 52, 53, and 55)

The thienopyridines include ticlopidine, clopidogrel, and prasugrel—drugs that target P2Y₁₂, a key ADP receptor on platelets.

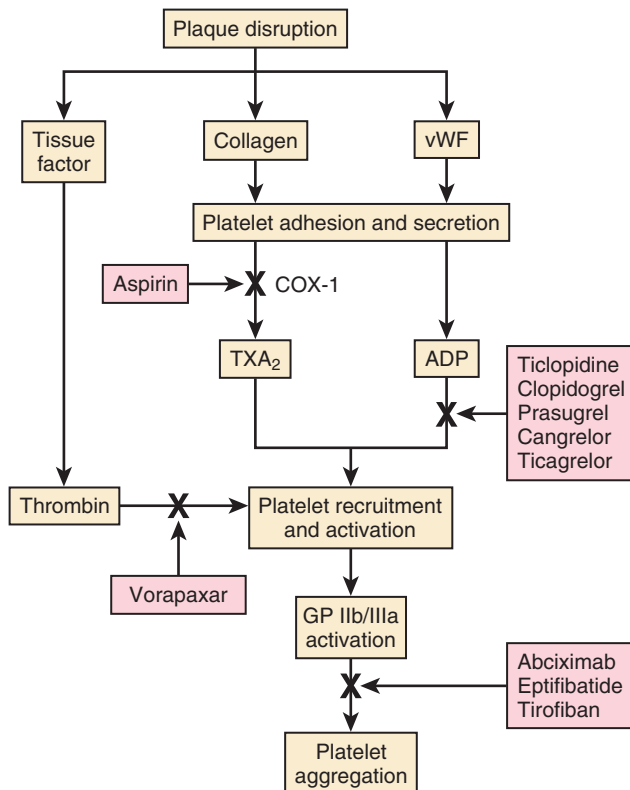

FIGURE 82-10 Sites of action of antiplatelet drugs. Aspirin inhibits the synthesis of thromboxane A_2 (TXA₂) by irreversibly acetylating COX-1. The reduced release of TXA₂ attenuates platelet activation and recruitment to the site of vascular injury. Ticlopidine, clopidogrel, and prasugrel irreversibly block P2Y₁₂, a key ADP receptor on the platelet surface; cangrelor and ticagrelor are reversible inhibitors of P2Y₁₂. Abciximab, eptifibatide, and tirofiban inhibit the final common pathway of platelet aggregation by blocking binding of fibrinogen and vWF to activated GP IIb/IIIa. Vorapaxar inhibits thrombin-mediated platelet activation by targeting PAR-1, the major thrombin receptor on platelets.

Mechanism of Action

The thienopyridines selectively inhibit ADP-induced platelet aggregation by irreversibly blocking P2Y₁₂ (see Fig. 82-10). Ticlopidine and clopidogrel are prodrugs that require metabolic activation by the hepatic cytochrome P-450 (CYP) enzyme system. Consequently, when given in usual doses, ticlopidine and clopidogrel have a delayed onset of action. Although prasugrel is also a prodrug that requires metabolic activation, its onset of action is more rapid than that of ticlopidine or clopidogrel, and it produces greater and more predictable inhibition of ADP-induced platelet aggregation.⁴² These characteristics reflect the rapid and complete absorption of prasugrel from the gut and its more efficient activation pathways. Although all of absorbed prasugrel undergoes activation, only 15% of absorbed clopidogrel undergoes metabolic activation; the remainder is inactivated by esterases. Ticlopidine is rarely used because of the risk for myelosuppression and because of the greater potency and better safety profile of newer drugs.

The active metabolites of the thienopyridines bind irreversibly to P2Y₁₂. Consequently, these drugs have prolonged action, which can present problems if patients require urgent surgery. To reduce the risk for bleeding, thienopyridine therapy must be stopped at least 5 days before surgery.

Indications

When compared with the use of aspirin in patients with recent ischemic stroke, myocardial infarction, or peripheral arterial disease, clopidogrel reduced the risk for cardiovascular death, myocardial infarction, and stroke by 8.7%. Therefore clopidogrel is marginally more effective than aspirin, but it is more expensive than aspirin, although the cost of clopidogrel has decreased now that generic forms are available. The combination of clopidogrel and aspirin capitalizes on their capacity to block complementary pathways of platelet activation. For example, this combination is recommended for at least 4 weeks after implantation of a bare metal stent in a coronary artery and for at least 1 year in those with a drug-eluting stent. Concerns about late in-stent thrombosis with drug-eluting stents have led some experts to recommend long-term dual-antiplatelet therapy for this indication, an issue currently under intense investigation (see Chapter 55).

The combination of clopidogrel and aspirin is also effective in patients with unstable angina. In 12,562 such patients, the risk for cardiovascular death, myocardial infarction, or stroke was 9.3% in those randomly assigned to the combination of clopidogrel and aspirin and 11.4% in those given aspirin alone. This 20% relative risk reduction with combination therapy was highly statistically significant. However, combining clopidogrel with aspirin increases the risk for major bleeding to approximately 2% per year—a risk that persists even with a daily aspirin dose of 100 mg or less.⁴³ Therefore use of clopidogrel plus aspirin should be restricted to situations in which there is clear evidence of benefit. For example, this combination has not proved to be superior to clopidogrel alone in patients with acute ischemic stroke⁴⁴ or to aspirin alone for primary prevention in those at risk for cardiovascular events.⁴⁵

Prasugrel was compared with clopidogrel in 13,608 patients with acute coronary syndromes scheduled to undergo percutaneous coronary intervention (PCI).⁴⁶ The incidence of the primary efficacy endpoint—a composite of cardiovascular death, myocardial infarction, and stroke—was significantly lower with prasugrel than with clopidogrel (9.9% and 12.1%, respectively), mainly because of a reduction in the incidence of nonfatal myocardial infarction. The incidence of stent thrombosis was also significantly lower with prasugrel than with clopidogrel (1.1% and 2.4%, respectively). These advantages, however, were at the expense of significantly higher rates of fatal bleeding (0.4% and 0.1%, respectively) and life-threatening bleeding (1.4% and 0.9%, respectively) with prasugrel. Because patients older than 75 years and those with a history of previous stroke or transient ischemic attack have a particularly high risk for bleeding, prasugrel should be avoided in older patients, and the drug is contraindicated in those with a history of cerebrovascular disease. Caution is required if prasugrel is used in patients weighing less than 60 kg or in those with renal impairment.

Dosing

Clopidogrel is given once daily at a dose of 75 mg.⁴² Because its onset of action is delayed for several days, 300- to 600-mg loading doses of clopidogrel are given when rapid ADP receptor blockade is desired (see Chapter 55). After a loading dose of 60 mg, prasugrel is given once daily at a dose of 10 mg. Patients older than 75 years or weighing less than 60 kg should receive a daily prasugrel dose of 5 mg.

Side Effects

The most common side effects of ticlopidine are gastrointestinal. More serious are hematologic side effects, which include neutropenia, thrombocytopenia, and thrombotic thrombocytopenic purpura. These side effects usually occur within the first few months of starting treatment. Therefore blood counts must be carefully monitored when initiating therapy with ticlopidine. Gastrointestinal and hematologic side effects are rare with clopidogrel and prasugrel.

Clopidogrel Resistance. The capacity of clopidogrel to inhibit ADP-induced platelet aggregation varies among subjects.⁴⁷ This variability reflects, at least in part, genetic polymorphisms in the CYP isoenzymes involved in the metabolic activation of clopidogrel (see also Chapters 7, 52, and 53). The most important of these enzymes is CYP2C19.^{48,49} Clopidogrel-treated patients with the loss-of-function CYP2C19*2 allele exhibit reduced platelet inhibition in comparison to those with the wild-type CYP2C19*1 allele and experience a higher rate of cardiovascular events.⁵⁰⁻⁵³ This is important because estimates suggest that up to 25% of whites, 30% of blacks, and 50% of Asians carry the loss-of-function allele, which may render them resistant to clopidogrel. Even patients with reduced-function CYP2C19*3, CYP2C19*4, or CYP2C19*5 alleles may derive less benefit from clopidogrel than do those with the full-function CYP2C19*1 allele. Patients with polymorphisms in ABCB1 may exhibit impaired clopidogrel absorption, and polymorphisms in CYP3A4 can contribute to reduced metabolic activation of clopidogrel. Polymorphisms in both these enzymes have been linked to adverse clinical outcomes. In contrast to their effect on the metabolic activation of clopidogrel, polymorphisms in CYP2C19 and CYP3A4 do not appear to influence activation of prasugrel, nor do they affect the response to ticagrelor.

Although concomitant administration of clopidogrel with proton pump inhibitors, which inhibit CYP2C19, reduces the effect of clopidogrel on ADP-induced platelet aggregation, this interaction has questionable clinical significance.⁵⁴ Atorvastatin, a competitive inhibitor of CYP3A4, reduced the inhibitory effect of clopidogrel on ADP-induced platelet aggregation in one study, a finding unconfirmed in subsequent investigations.⁵⁵

The influence of genetic polymorphisms on clinical outcomes with clopidogrel has raised the possibility that pharmacogenetic profiling and/or point-of-care platelet function testing could be used to identify clopidogrel-resistant patients so that they could be targeted for more intensive antiplatelet therapy.⁵⁶ Although up to 30% of clopidogrel-treated patients have evidence of reduced responsiveness to the drug, randomized clinical trials have failed to show that more intensive antiplatelet therapy improves outcome in such patients.^{57,58} Consequently, there is no indication for clopidogrel resistance testing at this time. Because their antiplatelet effects are more predictable, some guidelines recommend prasugrel or ticagrelor instead of clopidogrel for high-risk patients.

Dipyridamole

A relatively weak antiplatelet agent on its own,³⁷ an extended-release formulation of dipyridamole combined with low-dose aspirin, a preparation marketed as Aggrenox, is used for prevention of stroke in patients with transient ischemic attacks.

Mechanism of Action

By inhibiting phosphodiesterase, dipyridamole blocks the breakdown of cAMP. Increased levels of cAMP reduce intracellular calcium and inhibit platelet activation. Dipyridamole also blocks the uptake of adenosine by platelets and other cells. With more extracellular adenosine, there is a further increase in local cAMP levels because the platelet adenosine A₂ receptor and adenylate cyclase are coupled (Fig. 82-11).

Dosing

Aggrenox is given twice daily. Each capsule contains 200 mg of extended-release dipyridamole and 25 mg of aspirin.

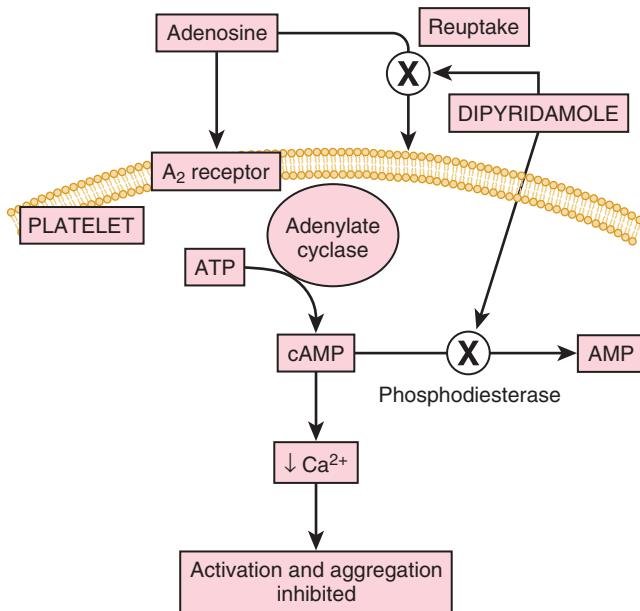

FIGURE 82-11 Mechanism of action of dipyridamole. Dipyridamole increases levels of cAMP in platelets by (1) blocking the reuptake of adenosine, thereby increasing the concentration of adenosine available to bind to the A₂ receptor, and (2) inhibiting phosphodiesterase-mediated cAMP degradation. By promoting calcium uptake, cAMP reduces intracellular levels of calcium. This, in turn, inhibits platelet activation and aggregation.

Side Effects

Because dipyridamole has vasodilatory effects, caution is necessary in patients with coronary artery disease. Gastrointestinal complaints, headache, facial flushing, dizziness, and hypotension can also occur. These symptoms often subside with continued use of the drug.

Indications

Dipyridamole plus aspirin was compared with aspirin or dipyridamole alone and with placebo in patients with an ischemic stroke or transient ischemic attack. The combination reduced the risk for stroke by 22.1% in comparison to aspirin and by 24.4% in comparison to dipyridamole.⁵⁹ A second trial compared dipyridamole plus aspirin with aspirin alone for secondary prevention in patients with ischemic stroke. Vascular death, stroke, or myocardial infarction occurred in 13% of patients given combination therapy and in 16% of those treated with aspirin alone. Although the combination of dipyridamole plus aspirin compares favorably with aspirin, the combination is not superior to clopidogrel. In a large randomized trial that compared dipyridamole plus aspirin with clopidogrel for secondary prevention in patients with ischemic stroke,⁶⁰ recurrent stroke event rates were similar (9.0% and 8.8%, respectively), as were rates of vascular death, stroke, and myocardial infarction (13.1% in both treatment arms). However, there was a trend toward more hemorrhagic strokes with dipyridamole plus aspirin than with clopidogrel (0.8% and 0.4%, respectively) and more major bleeding (4.1% and 3.8%, respectively).

Although Aggrenox can replace aspirin for stroke prevention, because of the vasodilatory effects of dipyridamole and the paucity of data supporting the usefulness of this drug in patients with symptomatic coronary artery disease, Aggrenox is contraindicated in such patients; clopidogrel is a better choice in patients with coronary artery disease.

Ticagrelor

As an orally active inhibitor of P2Y₁₂, ticagrelor differs from the thienopyridines in that it does not require metabolic activation and it produces reversible inhibition of the ADP receptor.

Mechanism of Action

Like the thienopyridines, ticagrelor inhibits P2Y₁₂. Because it does not require metabolic activation, ticagrelor has a more rapid onset and

offset of action than clopidogrel does and it produces greater and more predictable inhibition of ADP-induced platelet aggregation.

Dosing

Ticagrelor is initiated with an oral loading dose of 180 mg followed by 90 mg twice daily. The dose does not need adjustment in patients with renal impairment, but caution is needed in patients with hepatic impairment or in those receiving potent inhibitors or inducers of CYP3A4 because ticagrelor is metabolized in the liver via CYP3A4. Ticagrelor is usually administered in conjunction with aspirin; the daily aspirin dose should not exceed 100 mg.

Side Effects

In addition to bleeding, the most common side effects of ticagrelor are dyspnea, which can develop in up to 15% of patients, and asymptomatic ventricular pauses. The dyspnea, which tends to occur soon after initiating ticagrelor, is usually self-limited and mild in intensity. The mechanism responsible for this side effect is unknown.

Indications

When compared with clopidogrel in patients with acute coronary syndromes,⁶¹ ticagrelor produced a greater reduction in the primary efficacy endpoint—a composite of cardiovascular death, myocardial infarction, and stroke at 1 year—than did clopidogrel (9.8% and 11.7%, respectively; $P = .001$). This difference reflected a significant reduction in both cardiovascular death (4.0% and 5.1%, respectively; $P = .001$) and myocardial infarction (5.8% and 6.9%, respectively; $P = .005$) with ticagrelor relative to clopidogrel. Rates of stroke were similar with ticagrelor and clopidogrel (1.5% and 1.3%, respectively), and there was no difference in rates of major bleeding. When minor bleeding was added to the major bleeding results, however, ticagrelor showed an increase relative to clopidogrel (16.1% and 14.6%, respectively; $P = .008$). Ticagrelor was also superior to clopidogrel in patients with acute coronary syndrome who underwent PCI or cardiac surgery. Based on these observations, some guidelines give ticagrelor preference over clopidogrel, particularly in higher-risk patients.

Glycoprotein IIb/IIIa Receptor Antagonists

As a class, parenteral GP IIb/IIIa receptor antagonists have a niche in patients with acute coronary syndromes. The three agents in this class are abciximab, eptifibatide, and tirofiban.

Mechanism of Action

A member of the integrin family of adhesion receptors, GP IIb/IIIa is expressed on the surface of platelets and megakaryocytes. With approximately 80,000 copies per platelet, GP IIb/IIIa is the most abundant receptor. GP IIb/IIIa is inactive on resting platelets. With platelet activation, however, inside-outside signal transduction pathways trigger conformational activation of the receptor. Once activated, GP IIb/IIIa binds fibrinogen and, under high-shear conditions, vWF. Once bound, fibrinogen and vWF bridge adjacent platelets together to induce platelet aggregation.

Although abciximab, eptifibatide, and tirofiban all target the GP IIb/IIIa receptor, they are structurally and pharmacologically distinct (**Table 82-2**). Abciximab is a Fab fragment of a humanized murine monoclonal antibody directed against the activated form of GP IIb/IIIa.⁶² Abciximab binds to the activated receptor with high affinity and blocks the binding of adhesive molecules. In contrast to abciximab, eptifibatide and tirofiban are synthetic molecules.⁶² Eptifibatide is a cyclical heptapeptide that binds GP IIb/IIIa because it incorporates the KGD motif, whereas tirofiban is a nonpeptidic tyrosine derivative that acts as a RGD mimetic. With its long half-life, abciximab persists on the surface of platelets for up to 2 weeks. Eptifibatide and tirofiban have shorter half-lives.⁶²

In addition to targeting the GP IIb/IIIa receptor, abciximab (but not eptifibatide or tirofiban) also inhibits the closely related $\alpha_v\beta_3$ receptor, which binds vitronectin, and $\alpha_M\beta_2$, a leukocyte integrin. Inhibition of $\alpha_v\beta_3$ and $\alpha_M\beta_2$ may endow abciximab with anti-inflammatory and/or antiproliferative properties that extend beyond platelet inhibition.⁶²

**TABLE 82-2** Features of Glycoprotein IIb/IIIa Antagonists

FEATURE	ABCIXIMAB	EPTIFIBATIDE	TIROFIBAN
Description	Fab fragment of humanized mouse monoclonal antibody	Cyclical KGD-containing heptapeptide	Nonpeptidic RGD mimetic
Specific for GP IIb/IIIa	No	Yes	Yes
Plasma half-life	Short (min)	Long (2.5 hr)	Long (2.0 hr)
Platelet-bound half-life	Long (days)	Short (sec)	Short (sec)
Renal clearance	No	Yes	Yes

Dosing

All the GP IIb/IIIa antagonists are given as an intravenous bolus followed by an infusion. Because of their renal clearance, eptifibatide and tirofiban doses require reduction in patients with renal insufficiency.⁶²

Side Effects

In addition to bleeding, thrombocytopenia is the most serious complication. Antibodies directed against neoantigens on GP IIb/IIIa that are exposed on antagonist binding⁶³ cause thrombocytopenia, which is immune mediated. With abciximab, thrombocytopenia occurs in up to 5% of patients and is severe in approximately 1% of these individuals. Thrombocytopenia is less common with the other two agents and occurs in approximately 1% of patients.

Indications

Abciximab and eptifibatide are used in patients undergoing PCI, particularly those with acute myocardial infarction,^{64,65} whereas tirofiban and eptifibatide are used in high-risk patients with unstable angina.⁶⁴

Newer Antiplatelet Agents

New agents in advanced stages of development include cangrelor, a parenteral reversible P2Y₁₂ antagonist, and vorapaxar, an orally active inhibitor of PAR-1, the major thrombin receptor on platelets (see Fig. 82-10). The adenosine analogue cangrelor binds reversibly to P2Y₁₂ and inhibits its activity. The drug has a half-life of 3 to 6 minutes after intravenous administration. When stopped, platelet function recovers within 60 minutes. Recent trials comparing cangrelor with placebo during PCI or comparing cangrelor with clopidogrel after such procedures revealed little or no advantage of cangrelor.^{66,67} Consequently, identification of a role for cangrelor requires additional studies.

Vorapaxar was compared with placebo for secondary prevention in 26,449 patients with previous myocardial infarction, ischemic stroke, or peripheral arterial disease.⁶⁸ Overall, vorapaxar reduced the risk for cardiovascular death, myocardial infarction, or stroke by 13% but doubled the risk for intracranial bleeding. In the prespecified subgroup of 17,779 patients with previous myocardial infarction, however, vorapaxar reduced the risk for cardiovascular death, myocardial infarction, or stroke by 20% (from 9.7% to 8.1%). The rate of intracranial hemorrhage was higher with vorapaxar than with placebo (0.6% and 0.4%, respectively; $P = .076$), as was the rate of moderate or severe bleeding (3.4% and 2.1%, respectively; $P < .001$). Based on these data, the drug is now licensed for patients younger than 75 years with myocardial infarction who have no history of stroke or transient ischemic attack and weigh more than 60 kg.

Anticoagulants

There are parenteral and oral anticoagulants. Currently available parenteral anticoagulants include heparin, LMWH, and fondaparinux,

TABLE 82-3 Comparison of Features of Heparin, Low-Molecular-Weight Heparin, and Fondaparinux

FEATURES	HEPARIN	LMWH	FONDAPARINUX
Source	Biologic	Biologic	Synthetic
Molecular weight	15,000	5000	1500
Target	Xa and IIa	Xa and IIa	Xa
Bioavailability (%)	30	90	100
Half-life (hr)	1	4	17
Renal excretion	No	Yes	Yes
Antidote	Complete	Partial	No
HIT	<5%	<1%	Never

HIT = heparin-induced thrombocytopenia.

a synthetic pentasaccharide. Currently available oral anticoagulants include warfarin; dabigatran etexilate, an oral thrombin inhibitor; and rivaroxaban and apixaban, oral factor Xa inhibitors.⁶⁹

Parenteral Anticoagulants
Heparin

A sulfated polysaccharide, heparin is isolated from mammalian tissues rich in mast cells (Table 82-3). Most commercial heparin is derived from porcine intestinal mucosa and is a polymer of alternating D-glucuronic acid and N-acetyl-D-glucosamine residues.⁷⁰

MECHANISM OF ACTION. Heparin acts as an anticoagulant by activating antithrombin (previously known as antithrombin III) and accelerating the rate at which it inhibits clotting enzymes, particularly thrombin and factor Xa.⁷⁰ Antithrombin, the obligatory plasma cofactor for heparin, is a member of the serine protease inhibitor (serpin) superfamily. Synthesized in the liver and circulating in plasma at a concentration of $2.6 \pm 0.4 \mu\text{M}$, antithrombin acts as a suicide substrate for its target enzymes.

To activate antithrombin, heparin binds to the serpin via a unique pentasaccharide sequence found on a third of the chains of commercial heparin (Fig. 82-12). Heparin chains lacking this pentasaccharide sequence have little or no anticoagulant activity.⁷⁰ Once bound to antithrombin, heparin induces a conformational change in the reactive center loop of antithrombin that renders it more readily accessible to its target proteases. This conformational change enhances the rate at which antithrombin inhibits factor Xa by at least two orders of magnitude but has little effect on the rate of thrombin inhibition by antithrombin. To promote thrombin inhibition, heparin serves as a template that binds antithrombin and thrombin simultaneously. Formation of this ternary complex brings the enzyme in close apposition to the inhibitor, thereby promoting the formation of a stable covalent thrombin-antithrombin complex.⁷⁰

Only pentasaccharide-containing heparin chains composed of at least 18 saccharide units (which corresponds to a molecular weight of 5400) have sufficient length to bridge thrombin and antithrombin together.⁷⁰ With a mean molecular weight of 15,000 and a range of 5000 to 30,000, almost all the chains of unfractionated heparin are long enough to provide this bridging function. Consequently, by definition, heparin has equal capacity to promote inhibition of thrombin and factor Xa by antithrombin and has an anti-factor Xa-to-anti-factor IIa (thrombin) ratio of 1:1. Heparin causes the release of TFPI from the endothelium. A factor Xa-dependent inhibitor of tissue factor-bound factor VIIa,⁸ TFPI may contribute to the antithrombotic activity of heparin. Longer heparin chains induce the release of more TFPI than shorter chains do.

PHARMACOLOGY OF HEPARIN. Heparin requires parenteral administration and is usually administered subcutaneously or by continuous intravenous infusion. When given for therapeutic purposes, the intravenous route is most often used. If administered subcutaneously for the treatment of thrombosis, the dose must be high enough to overcome the limited bioavailability associated with this method of delivery.

FIGURE 82-12 Mechanism of action of heparin, LMWH, and fondaparinux, a synthetic pentasaccharide. **A**, Heparin binds to antithrombin via its pentasaccharide sequence. This induces a conformational change in the reactive center loop of antithrombin that accelerates its interaction with factor Xa. To potentiate thrombin inhibition, heparin must simultaneously bind to antithrombin and thrombin. Only heparin chains composed of at least 18 saccharide units, which corresponds to a molecular weight of 5400, are of sufficient length to perform this bridging function. With a mean molecular weight of 15,000, all the heparin chains are long enough to do this. **B**, LMWH has greater capacity to potentiate factor Xa inhibition by antithrombin than thrombin does because with a mean molecular weight of 4500 to 6000, at least half of the LMWH chains are too short to bridge antithrombin to thrombin. **C**, Fondaparinux, a synthetic pentasaccharide, accelerates inhibition of factor Xa only by antithrombin because it is too short to bridge antithrombin to thrombin.

In the circulation, heparin binds to the endothelium and to plasma proteins other than antithrombin. Binding of heparin to endothelial cells explains its dose-dependent clearance. At low doses, the half-life of heparin is short because it rapidly binds to the endothelium. With higher doses of heparin, the half-life is longer because heparin clearance is slower once the endothelium is saturated. Clearance is mainly extrarenal; heparin binds to macrophages, which internalize and depolymerize the long heparin chains and secrete shorter chains back into the circulation. Because of its dose-dependent clearance mechanism, the plasma half-life of heparin ranges from 30 to 60 minutes with bolus intravenous doses of 25 and 100 units/kg, respectively.

Once heparin enters the circulation, it binds to plasma proteins other than antithrombin, a phenomenon that reduces the anticoagulant activity of heparin. Some of the heparin-binding proteins found in plasma are acute-phase reactants whose levels are elevated in ill patients. Activated platelets or endothelial cells release other proteins that can bind heparin, such as large multimers of vWF. Activated platelets also release platelet factor 4 (PF4), a highly cationic protein that binds heparin with high affinity. The large amounts of PF4 associated with platelet-rich arterial thrombi can neutralize the anticoagulant activity of heparin. This phenomenon may attenuate heparin's capacity to suppress thrombus growth.

Because levels of heparin binding-proteins in plasma vary from person to person, the anticoagulant response to fixed or weight-adjusted doses of heparin is unpredictable. Consequently, monitoring of coagulation is essential to ensure a therapeutic response, particularly when heparin is administered for the treatment of established thrombosis because a subtherapeutic anticoagulant response may

render patients at risk for recurrent thrombosis whereas excessive anticoagulation increases the risk for bleeding.

MONITORING THE ANTICOAGULANT EFFECT OF HEPARIN. The APTT or anti-factor Xa level is used to monitor heparin.⁷⁰ Although the APTT is the test most often used for this purpose, there are problems with the assay: APTT reagents vary in their sensitivity to heparin, and the type of coagulometer used for testing can influence the results. Consequently, laboratories must establish a therapeutic APTT range with each reagent-coagulometer combination by measuring both the APTT and anti-factor Xa levels in plasma samples collected from heparin-treated patients. With most APTT reagents and coagulometers in current use, heparin levels are therapeutic with a twofold to threefold prolongation of the APTT.

Anti-factor Xa levels can also be used to monitor heparin therapy. With this test, therapeutic heparin levels range from 0.3 to 0.7 units/mL. Although this test is gaining in popularity, anti-factor Xa assays have yet to be standardized, and results can vary widely between laboratories.

Up to 25% of patients with VTE are heparin resistant; they require more than 35,000 units/day to achieve a therapeutic APTT. It is useful to measure anti-factor Xa levels in heparin-resistant patients because many will have a therapeutic anti-factor Xa level despite a subtherapeutic APTT. This dissociation in test results occurs because elevated plasma levels of fibrinogen and factor VIII, both acute-phase proteins, shorten the APTT but have no effect on anti-factor Xa levels.⁷¹ Anti-factor Xa levels are better than the APTT for monitoring heparin in patients who exhibit this phenomenon. Patients with congenital or acquired antithrombin deficiency and those with elevated levels of heparin-binding proteins may also need high doses of heparin to achieve a therapeutic APTT or anti-factor Xa level. If there is good correlation between the APTT and the anti-factor Xa level, either test can be used for monitoring heparin therapy.

DOSING. For prophylaxis, heparin is usually given in fixed doses of 5000 units subcutaneously two or three times daily. With these low doses, monitoring of coagulation is unnecessary. In contrast, monitoring is essential when the drug is given in therapeutic doses. Fixed-dose or weight-based heparin nomograms are used to standardize heparin dosing and to shorten the time required to achieve a therapeutic anticoagulant response. At least two heparin nomograms have been validated in patients with VTE, and both reduce the time required to achieve a therapeutic APTT. Weight-adjusted heparin nomograms have also been evaluated in patients with acute coronary syndromes. After an intravenous heparin bolus of 5000 units or 70 units/kg, a heparin infusion rate of 12 to 15 units/kg/hr is usually administered.⁷⁰ In contrast, weight-adjusted heparin nomograms for patients with VTE use an initial bolus of 5000 units or 80 units/kg followed by an infusion of 18 units/kg/hr. Thus achievement of a therapeutic APTT requires higher doses of heparin in patients with VTE than in those with acute coronary syndromes. This may reflect differences in thrombus burden. Heparin binds to fibrin, and the fibrin content of extensive deep vein thrombi is greater than that of small coronary thrombi.

Heparin manufacturers in North America measure heparin potency in USP units, with a unit defined as the concentration of heparin that prevents 1 mL of citrated sheep plasma from clotting for 1 hour after the addition of calcium. In contrast, manufacturers in Europe measure heparin potency with anti-Xa assays that use an international heparin standard for comparison. Because of problems with heparin contamination by oversulfated chondroitin sulfate,⁷² which the USP assay system does not detect, North American heparin manufacturers now use the anti-Xa assay to measure heparin potency. Use of international units in place of USP units results in a 10% to 15% reduction in the heparin dose. This change is unlikely to affect patient care because dosing of heparin has been done this way in Europe for many years. Furthermore, heparin monitoring ensures a therapeutic anticoagulant response in high-risk situations, such as cardiopulmonary bypass surgery or PCI.

LIMITATIONS OF HEPARIN. Heparin has pharmacokinetic and biophysical limitations (Table 82-4). The pharmacokinetic limitations reflect heparin's propensity to bind in a pentasaccharide-independent

**TABLE 82-4 Pharmacokinetic and Biophysical Limitations of Heparin**

LIMITATIONS	MECHANISM
Poor bioavailability	Limited absorption of long heparin chains
Dose-dependent clearance	Binds to endothelial cells
Variable anticoagulant response	Binds to plasma proteins; levels vary from patient to patient
Reduced activity in the vicinity of platelet-rich thrombi	Neutralized by PF4 released from activated platelets
Limited activity against factor Xa incorporated into the prothrombinase complex and thrombin bound to fibrin	Reduced capacity of heparin-antithrombin complex to inhibit factor Xa bound to activated platelets and thrombin

fashion to cells and plasma proteins. Binding of heparin to endothelial cells explains its dose-dependent clearance, whereas binding to plasma proteins results in a variable anticoagulant response and can lead to heparin resistance.

The biophysical limitations of heparin reflect the inability of the heparin-antithrombin complex to inhibit factor Xa when it is incorporated into the prothrombinase complex, the complex that converts prothrombin to thrombin, and to inhibit thrombin bound to fibrin. Consequently, factor Xa bound to activated platelets within platelet-rich thrombi can generate thrombin, even in the presence of heparin. Thrombin bound to fibrin protects it from inhibition by the heparin-antithrombin complex. Clot-associated thrombin can then trigger growth of thrombi by locally activating platelets and amplifying its own generation through feedback activation of factors V, VIII, and XI. Neutralization of heparin by the high concentrations of PF4 released from activated platelets within the platelet-rich thrombus further compounds this problem.

SIDE EFFECTS. The most common side effect of heparin is bleeding. Other complications include thrombocytopenia, osteoporosis, and elevated levels of transaminases.

BLEEDING. The risk for heparin-induced bleeding increases with higher heparin doses. Concomitant administration of drugs that affect hemostasis, such as antiplatelet or fibrinolytic agents, increases the risk for bleeding, as does recent surgery or trauma.⁷¹ Protamine sulfate will neutralize heparin in patients with serious bleeding. A mixture of basic polypeptides isolated from salmon sperm, protamine sulfate binds heparin with high affinity to form protamine-heparin complexes that undergo renal clearance. Typically, 1 mg of intravenous protamine sulfate neutralizes 100 units of heparin. Anaphylactoid reactions to protamine sulfate can occur, but administration by slow intravenous infusion reduces the risk for this problem.⁷⁰

THROMBOCYTOPENIA. Heparin-induced thrombocytopenia (HIT) is an antibody-mediated process triggered by antibodies against neoantigens on PF4 that are exposed when heparin binds to this protein.⁷³ These antibodies, which are usually of the IgG subtype, bind simultaneously to the heparin-PF4 complex and to platelet Fc receptors. Such binding activates the platelets and generates platelet microparticles. Circulating microparticles are procoagulant because they express anionic phospholipids on their surface and can bind clotting factors, thereby promoting thrombin generation.

Typically, HIT occurs 5 to 14 days after the initiation of heparin therapy, but it may be manifested earlier if the patient has received heparin within the past 3 months (Table 82-5). Even a 50% decrease in the platelet count from the pretreatment value should raise suspicion of HIT in those receiving heparin. HIT is more common in surgical patients than in medical patients and, like many autoimmune disorders, occurs more frequently in females than in males.⁷³

HIT can be associated with either arterial or venous thrombosis. Venous thrombosis, which is manifested as deep vein thrombosis and/or pulmonary embolism, is more common than arterial thrombosis. Arterial thrombosis can be manifested as ischemic stroke or

TABLE 82-5 Features of Heparin-Induced Thrombocytopenia

FEATURE	DETAILS
Thrombocytopenia	Platelet count of $\leq 100,000/\mu\text{L}$ or a decrease in platelet count of $\geq 50\%$ from baseline
Timing	Platelet count falls 5-14 days after starting heparin
Type of heparin	More common with unfractionated heparin than with LMWH
Type of patient	More common in surgical patients than in medical patients; more common in women than in men
Thrombosis	Venous thrombosis more common than arterial thrombosis

TABLE 82-6 Management of Heparin-Induced Thrombocytopenia

Stop all heparin.
Give an alternative anticoagulant, such as lepirudin, argatroban, bivalirudin, or fondaparinux.
Do not give platelet transfusions.
Do not give warfarin until the platelet count returns to baseline levels; if warfarin was administered, give vitamin K to restore the INR to normal.
Evaluate for thrombosis, particularly deep vein thrombosis.

acute myocardial infarction. Rarely, platelet-rich thrombi in the distal aorta or iliac arteries can cause critical limb ischemia.

The diagnosis of HIT is established via enzyme-linked assays to detect antibodies against heparin-PF4 complexes or via platelet activation assays. Enzyme-linked assays are sensitive but are not specific and can be positive even in the absence of any clinical evidence of HIT.⁷⁴ The most specific diagnostic test is the serotonin release assay. This test involves quantification of serotonin release after exposure of washed platelets loaded with labeled serotonin to patient serum in the absence or presence of various concentrations of heparin. If the patient's serum contains HIT antibody, the addition of heparin induces platelet activation and subsequent serotonin release.

To manage HIT, heparin therapy should be stopped in patients with suspected or documented HIT, and an alternative anticoagulant should be administered to prevent or treat thrombosis (Table 82-6).⁷³ The agents most often used for this indication are parenteral direct thrombin inhibitors, such as lepirudin, argatroban, or bivalirudin, or factor Xa inhibitors, such as fondaparinux.

Patients with HIT, particularly those with associated thrombosis, often have evidence of increased thrombin generation, which can lead to consumption of protein C. If these patients receive warfarin without a concomitant parenteral anticoagulant, the further decrease in protein C levels induced by the vitamin K antagonist can trigger skin necrosis. To avoid this problem, patients with HIT require treatment with a direct thrombin inhibitor or fondaparinux until the platelet count returns to normal levels. At this point, low-dose warfarin therapy can be introduced, and the thrombin inhibitor or fondaparinux can be discontinued when the anticoagulant response to warfarin has been therapeutic for at least 2 days.

OSTEOPOROSIS. Treatment with therapeutic doses of heparin for more than a month can cause a reduction in bone density. This occurs in up to 30% of patients treated long-term with heparin,⁷⁰ and symptomatic vertebral fractures occur in 2% to 3% of these individuals.

Studies in vitro and in laboratory animals have provided insight into the pathogenesis of heparin-induced osteoporosis. These investigations suggest that heparin causes bone resorption by decreasing bone formation and enhancing bone resorption. Thus heparin affects the activity of both osteoclasts and osteoblasts.

ELEVATED LEVELS OF TRANSAMINASES. Therapeutic doses of heparin frequently cause modest elevation in serum levels of hepatic transaminases without a concomitant increase in the level of

TABLE 82-7 Advantages of Low-Molecular-Weight Heparin and Fondaparinux over Heparin

ADVANTAGE	CONSEQUENCE
Better bioavailability and longer half-life after subcutaneous injection	Can be given subcutaneously once or twice daily for both prophylaxis and treatment
Dose-independent clearance	Simplified dosing
Predictable anticoagulant response	Monitoring of coagulation is unnecessary in most patients
Lower risk for HIT	Safer than heparin for short- or long-term administration
Lower risk for osteoporosis	Safer than heparin for long-term administration

bilirubin. Levels of transaminases rapidly return to normal when use of the drug is stopped. The mechanism responsible for this phenomenon is unknown.

Low-Molecular-Weight Heparin

Consisting of smaller fragments of heparin, LMWH is prepared from unfractionated heparin by controlled enzymatic or chemical depolymerization. The mean molecular weight of LMWH is 5000, one third the mean molecular weight of unfractionated heparin.⁷⁰ Because of its advantages over heparin (Table 82-7), LMWH has replaced heparin for many indications.

MECHANISM OF ACTION. Like heparin, LMWH exerts its anticoagulant activity by activating antithrombin. With a mean molecular weight of 5000, which corresponds to approximately 17 saccharide units, at least half of the pentasaccharide-containing chains of LMWH are too short to bridge thrombin to antithrombin (Fig. 82-12). These chains retain the capacity to accelerate inhibition of factor Xa by antithrombin because this activity results largely from the conformational changes in antithrombin evoked by pentasaccharide binding. Consequently, LMWH catalyzes inhibition of factor Xa by antithrombin more than inhibition of thrombin.⁷⁰ Depending on their unique molecular weight distributions, LMWH preparations have anti-factor Xa-to-anti-factor IIa ratios ranging from 2:1 to 4:1 (see Table 82-3).

PHARMACOLOGY OF LOW-MOLECULAR-WEIGHT HEPARIN. Although usually given subcutaneously, LMWH can be administered intravenously if a rapid anticoagulant response is needed. LMWH has pharmacokinetic advantages over heparin. These advantages arise because the shorter heparin chains bind less avidly to endothelial cells, macrophages, and heparin-binding plasma proteins. Reduced binding to endothelial cells and macrophages eliminates the rapid, dose-dependent, and saturable mechanism of clearance that is a characteristic of unfractionated heparin. Instead, clearance of LMWH is not dose dependent and its plasma half-life is longer. Based on measurement of anti-factor Xa levels, LMWH has a plasma half-life of approximately 4 hours. Because of its renal clearance, LMWH can accumulate in patients with renal insufficiency.

LMWH exhibits approximately 90% bioavailability after subcutaneous injection.⁷⁰ Because LMWH binds less avidly to heparin-binding proteins in plasma than heparin does, LMWH produces a more predictable dose response, and resistance to LMWH is rare. With a longer half-life and more predictable anticoagulant response, LMWH can be given subcutaneously once or twice daily without monitoring coagulation, even when the drug is administered in treatment doses. These properties render LMWH more convenient than unfractionated heparin. Capitalizing on this feature, studies in patients with VTE have shown that home treatment with LMWH is as effective and safe as in-hospital treatment with continuous intravenous infusions of heparin.⁷¹ Outpatient treatment with LMWH streamlines care, reduces health care costs, and increases patient satisfaction.

MONITORING OF LOW-MOLECULAR-WEIGHT HEPARIN. In most patients, LMWH does not require monitoring of coagulation. If monitoring is necessary, the anti-factor Xa level is measured because most LMWH preparations have little effect on the APTT. Therapeutic

anti-factor Xa levels with LMWH range from 0.5 to 1.2 units/mL when measured 3 to 4 hours after drug administration. With prophylactic doses of LMWH, peak anti-factor Xa levels of 0.2 to 0.5 units/mL are desirable.⁷⁰

Situations that may require LMWH monitoring include renal insufficiency and obesity. Monitoring of LMWH in patients with a creatinine clearance of 50 mL/min or less is advisable to ensure that no drug accumulation takes place. Although weight-adjusted LMWH dosing appears to produce therapeutic anti-factor Xa levels in overweight patients, this approach has not been well studied in those with morbid obesity. It may also be advisable to monitor the anticoagulant activity of LMWH during pregnancy because dose requirements can change, particularly in the third trimester. Monitoring should also be considered in high-risk settings, such as in patients with mechanical heart valves who are given LMWH for prevention of valve thrombosis.

DOSING OF LOW-MOLECULAR-WEIGHT HEPARIN. The doses of LMWH recommended for prophylaxis or treatment vary depending on the preparation. For prophylaxis, once-daily subcutaneous doses of 4000 to 5000 units are often used, whereas doses of 2500 to 3000 units are given when the drug is administered twice daily. For treatment of VTE, a dose of 150 to 200 units/kg is given if the drug is administered once daily. If a twice-daily regimen is used, a dose of 100 units/kg is given. In patients with unstable angina, LMWH is administered subcutaneously twice daily at a dose of 100 to 120 units/kg. The dose is reduced in patients with renal impairment.

SIDE EFFECTS. The major complication of LMWH is bleeding. Meta-analyses suggest that the risk for major bleeding may be lower with LMWH than with unfractionated heparin. HIT and osteoporosis are less common with LMWH than with unfractionated heparin.

BLEEDING. The risk for bleeding with LMWH increases when antiplatelet or fibrinolytic drugs are given concomitantly.⁷¹ Recent surgery, trauma, or underlying hemostatic defects also increase the risk for bleeding with LMWH.

Although protamine sulfate serves as an antidote for LMWH, it incompletely neutralizes the anticoagulant activity of LMWH because it binds only the longer chains.⁷⁰ Because longer chains are responsible for catalysis of thrombin inhibition by antithrombin, protamine sulfate completely reverses the anti-factor IIa activity of LMWH. In contrast, protamine sulfate only partially reverses the anti-factor Xa activity of LMWH because the shorter pentasaccharide-containing chains of LMWH do not bind protamine sulfate. Consequently, continuous intravenous unfractionated heparin may be safer than subcutaneous LMWH for patients at high risk for bleeding.

THROMBOCYTOPENIA. The risk for HIT is about fivefold lower with LMWH than with heparin.⁷³ LMWH binds less avidly to platelets and causes less release of PF4. Furthermore, with lower affinity for PF4 than for heparin, LMWH is less likely to induce the conformational changes in PF4 that trigger the formation of HIT antibodies. LMWH should not be used to treat patients with HIT because most HIT antibodies exhibit cross-reactivity with LMWH. This in vitro cross-reactivity is not simply a laboratory phenomenon; there are case reports of thrombosis in HIT patients treated with LMWH.

OSTEOPOROSIS. The risk for osteoporosis is lower with long-term LMWH than with heparin.⁷⁰ For extended treatment, therefore, LMWH is a better choice than heparin because of the lower risk for osteoporosis and HIT.

Fondaparinux

A synthetic analogue of the antithrombin-binding pentasaccharide sequence, fondaparinux differs from LMWH in several ways (see Table 82-3). Fondaparinux is licensed for thromboprophylaxis in medical, general surgical, and high-risk orthopedic patients and as an alternative to heparin or LMWH for the initial treatment of patients with established VTE. Although fondaparinux is licensed as an alternative to heparin or LMWH in patients with acute coronary syndrome in Europe and Canada, it is not approved for this indication in the United States.

MECHANISM OF ACTION. As a synthetic analogue of the antithrombin-binding pentasaccharide sequence found in heparin

and LMWH, fondaparinux has a molecular weight of 1728. Fondaparinux binds only to antithrombin (Fig. 82-12) and is too short to bridge thrombin to antithrombin. Consequently, fondaparinux catalyzes inhibition of factor Xa by antithrombin and does not enhance the rate of thrombin inhibition.⁷⁰

PHARMACOLOGY OF FONDAPARINUX. Fondaparinux exhibits complete bioavailability after subcutaneous injection. With no binding to endothelial cells or plasma proteins, clearance of fondaparinux is independent of dose and its plasma half-life is 17 hours. The drug is administered subcutaneously once daily. Because of its renal clearance, fondaparinux is contraindicated in patients with creatinine clearance lower than 30 mL/min, and it should be used with caution in those with a creatinine clearance lower than 50 mL/min.⁷⁰

Fondaparinux produces a predictable anticoagulant response after administration in fixed doses because it does not bind to plasma proteins. The drug is given at a dosage of 2.5 mg once daily for prevention of VTE. For initial treatment of established VTE, fondaparinux is given at a dosage of 7.5 mg once daily. The dosage can be reduced to 5 mg once daily for those weighing less than 50 kg and increased to 10 mg for those heavier than 100 kg. When given in these doses, fondaparinux is as effective as heparin or LMWH for the initial treatment of patients with deep vein thrombosis or pulmonary embolism and produces similar rates of bleeding.^{75,76}

Fondaparinux is used at a dosage of 2.5 mg once daily in patients with acute coronary syndromes. When this prophylactic dose of fondaparinux was compared with treatment doses of enoxaparin in patients with non-ST-segment elevation acute coronary syndrome, no difference in the rate of cardiovascular death, myocardial infarction, or stroke was seen at 9 days.⁷⁷ The rate of major bleeding, however, was 50% lower with fondaparinux than with enoxaparin, which resulted in a 17% reduction in mortality at 1 month with fondaparinux. In patients with acute coronary syndromes who require PCI, there is a risk for catheter thrombosis with fondaparinux unless adjunctive heparin is given.

SIDE EFFECTS. Although fondaparinux can induce the formation of HIT antibodies, HIT does not occur.⁷⁸ This apparent paradox reflects the fact that induction of HIT requires heparin chains of sufficient length to bind multiple PF4 molecules. Fondaparinux is too short to do so. In contrast to LMWH, there is no cross-reactivity of fondaparinux with HIT antibodies. Consequently, fondaparinux appears to be effective for the treatment of HIT, although large clinical trials supporting its use are lacking.

The major side effect of fondaparinux is bleeding, and it has no antidote. Protamine sulfate has no effect on the anticoagulant activity of fondaparinux because it fails to bind to the drug. Recombinant activated factor VII has reversed the anticoagulant effects of fondaparinux in volunteers, but it is unknown whether this agent controls fondaparinux-induced bleeding.

Parenteral Direct Thrombin Inhibitors

Heparin and LMWH indirectly inhibit thrombin because they require antithrombin to exert their anticoagulant activity. In contrast, direct thrombin inhibitors do not require a plasma cofactor; instead, they bind directly to thrombin and block its interaction with its substrates. Approved parenteral direct thrombin inhibitors include lepirudin, argatroban, and bivalirudin (Table 82-8). Lepirudin and argatroban are licensed for the treatment of HIT, whereas bivalirudin is approved as an alternative to heparin in patients undergoing PCI, including those with HIT.

Lepirudin

A recombinant form of hirudin, lepirudin is a bivalent direct thrombin inhibitor that interacts with the active site of thrombin and with exosite 1, the substrate binding site.⁷⁰ For rapid anticoagulation, lepirudin is given by continuous intravenous infusion, but the drug can be administered subcutaneously for thromboprophylaxis. Lepirudin has a plasma half-life of 60 minutes after intravenous infusion and is cleared by the kidneys. Consequently, lepirudin accumulates in patients with renal insufficiency. Antibodies against the drug develop

TABLE 82-8 Comparison of the Properties of Hirudin, Bivalirudin, and Argatroban

	HIRUDIN	BIVALIRUDIN	ARGATROBAN
Molecular mass	7000	1980	527
Site or sites of interaction with thrombin	Active site and exosite 1	Active site and exosite 1	Active site
Renal clearance	Yes	No	No
Hepatic metabolism	No	No	Yes
Plasma half-life (min)	60	25	45

in a high proportion of lepirudin-treated patients. Although these antibodies rarely cause problems, in a small subset of patients they can delay lepirudin clearance and enhance its anticoagulant activity; some of these patients experience serious bleeding.

Lepirudin is usually monitored with the APTT, and the dose is adjusted to maintain an APTT 1.5 to 2.5 times control. The APTT is not an ideal test for monitoring lepirudin therapy because the clotting time plateaus with higher drug concentrations. Although the ecarin clotting time provides a better index of the lepirudin dose than the APTT does, the ecarin clotting time has yet to be standardized, and the test is not available in all coagulation laboratories.

Argatroban

Argatroban, a univalent inhibitor that targets the active site of thrombin, is metabolized in the liver.⁷⁰ Consequently, it must be used with caution in patients with hepatic insufficiency. Because it is not cleared by the kidneys, argatroban is safer than lepirudin for patients with HIT and renal impairment.

Argatroban is administered by continuous intravenous infusion and has a plasma half-life of approximately 45 minutes. The APTT is used to monitor its anticoagulant effect and the dose is adjusted to achieve an APTT 1.5 to 3 times the baseline value, but not to exceed 100 seconds. Argatroban also prolongs the international normalized ratio (INR), a feature that can complicate transitioning of patients to warfarin. This problem can be circumvented by using levels of factor X in place of the INR to monitor warfarin. Alternatively, the argatroban infusion can be stopped for 2 to 3 hours before determination of the INR.

Bivalirudin

A synthetic 20-amino acid analogue of hirudin, bivalirudin is a divalent thrombin inhibitor.⁷⁰ Thus the NH₂-terminal portion of bivalirudin interacts with the active site of thrombin, whereas its COOH-terminal tail binds to exosite 1, the substrate binding domain on thrombin. Bivalirudin has a plasma half-life of 25 minutes, the shortest half-life of all the parenteral direct thrombin inhibitors. It is degraded by peptidases and is partially excreted via the kidneys. When given in high doses in the cardiac catheterization laboratory, the anticoagulant activity of bivalirudin is monitored with the activated clotting time. With lower doses, its activity can be assessed via the APTT.

Studies comparing bivalirudin with heparin suggest that bivalirudin produces less bleeding. This feature, plus its short half-life, renders bivalirudin an attractive alternative to heparin in patients undergoing PCI. Bivalirudin has also been used successfully in patients with HIT who require PCI.⁷¹

Oral Anticoagulants

Vitamin K antagonists were identified more than 60 years ago during investigations of the cause of hemorrhagic disease in cattle. Characterized by decreased prothrombin levels, this disorder occurs after the ingestion of hay containing spoiled sweet clover. Hydroxycoumarin, which was isolated from bacterial contaminants in the hay,

interferes with vitamin K metabolism, thereby causing a syndrome similar to vitamin K deficiency. This compound spawned the development of other vitamin K antagonists, including warfarin.

Warfarin

A water-soluble vitamin K antagonist initially developed as a rodenticide, warfarin is the coumarin derivative most often prescribed in North America. Like other vitamin K antagonists, warfarin interferes with the synthesis of vitamin K–dependent clotting proteins, which include prothrombin (factor II) and factors VII, IX, and X. Warfarin also impairs synthesis of the vitamin K–dependent anticoagulant proteins C and S.⁷⁹

MECHANISM OF ACTION. All the vitamin K–dependent clotting factors possess glutamic acid residues at their N-terminals. A post-translational modification adds a carboxyl group to the gamma carbon of these residues to generate gamma-carboxyglutamic acid. This modification is essential for expression of the activity of these clotting factors because it permits calcium-dependent binding of them to anionic phospholipid surfaces. The gamma-carboxylation process is catalyzed by a vitamin K–dependent carboxylase. Thus vitamin K from the diet undergoes reduction to vitamin K hydroquinone by vitamin K reductase (Fig. 82-13). Vitamin K hydroquinone serves as a cofactor for the carboxylase enzyme, which in the presence of carbon dioxide, replaces the hydrogen on the gamma carbon of glutamic acid residues with a carboxyl group. During this process, vitamin K hydroquinone is oxidized to vitamin K epoxide, which then undergoes reduction to vitamin K in a reaction catalyzed by vitamin K epoxide reductase.

Warfarin inhibits vitamin K epoxide reductase, thereby blocking the gamma-carboxylation process. This results in the synthesis of partially gamma-carboxylated clotting proteins with little or no

biologic activity. Warfarin exerts its anticoagulant activity when the newly synthesized clotting factors with reduced activity gradually replace their fully active counterparts.

The antithrombotic effect of warfarin requires a reduction in the functional levels of factor X and prothrombin, clotting factors with half-lives of 24 and 72 hours, respectively.⁸⁰ Because the antithrombotic effect of warfarin is delayed, patients with established thrombosis or at high risk for thrombosis require concomitant treatment with a rapidly acting parenteral anticoagulant, such as heparin, LMWH, or fondaparinux.⁷⁹

PHARMACOLOGY. Warfarin is a racemic mixture of *R*- and *S*-isomers. It is rapidly and almost completely absorbed from the gastrointestinal tract. Levels of warfarin in blood peak approximately 90 minutes after administration. Racemic warfarin has a plasma half-life of 36 to 42 hours, and more than 97% of circulating warfarin is bound to albumin. Only the small fraction of unbound warfarin is biologically active.⁷⁹

Warfarin accumulates in the liver, where the two isomers are metabolized via distinct pathways. The more active *S*-enantiomer of warfarin is primarily metabolized by CYP2C9 (see Fig. 82-12). Two relatively common variants, *CYP2C9*2* and *CYP2C9*3*, encode an enzyme with reduced activity. Approximately 25% of whites have at least one variant allele of *CYP2C9*2* or *CYP2C9*3*; these variant alleles are less common in blacks and Asians (Table 82-9). Patients with one variant allele require 20% to 30% lower maintenance doses of warfarin, whereas those homozygous for these alleles require 50% to 70% lower doses than do those with the wild-type *CYP2C9*1* alleles. Consistent with the decreased warfarin dose requirement, subjects with at least one *CYP2C9* variant allele are at increased risk for bleeding. Thus when compared with individuals with no variant alleles, the relative risk for warfarin-associated bleeding in *CYP2C9*2* or *CYP2C9*3* carriers is 1.9 and 1.8, respectively.^{80,81}

Warfarin interferes with the vitamin K cycle by inhibiting the C1 subunit of vitamin K epoxide reductase (VKORC1).⁸²⁻⁸⁴ Polymorphisms in *VKORC1* can influence the anticoagulant response to warfarin. Several genetic variations of *VKORC1* are in strong linkage disequilibrium and have been designated as non-A haplotypes. *VKORC1* variants are more prevalent than variants of *CYP2C9*. Asians have the highest prevalence of *VKORC1* variants, followed by whites and blacks. Warfarin dose requirements for subjects heterozygous or homozygous for the A haplotype are 25% and 50% lower, respectively, than the dose needed for subjects with the non-A/non-A haplotype. Polymorphisms in *CYP2C9* and *VKORC1* explain up to 25% of the variability in warfarin dose requirements.⁸¹⁻⁸⁴ These findings prompted

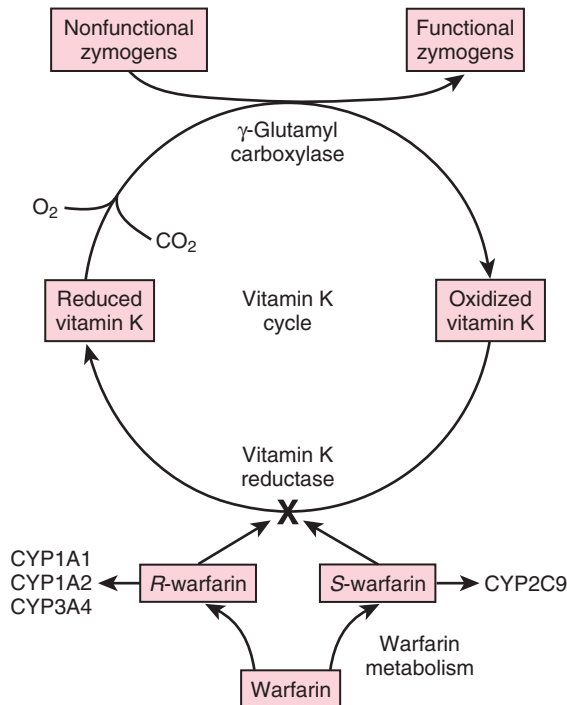

FIGURE 82-13 Mechanism of action of warfarin. A racemic mixture of *S*- and *R*-enantiomers, *S*-warfarin is most active. By blocking vitamin K epoxide reductase, warfarin inhibits the conversion of oxidized vitamin K into its reduced form. This inhibits vitamin K–dependent gamma-carboxylation of factors II, VII, IX, and X because reduced vitamin K serves as a cofactor for a gamma-glutamylcarboxylase, which catalyzes the gamma-carboxylation process, thereby converting prozymogens to zymogens capable of binding calcium and interacting with anionic phospholipid surfaces. *S*-warfarin is metabolized by CYP2C9. Common genetic polymorphisms in this enzyme can influence the metabolism of warfarin. Polymorphisms in the C1 subunit of vitamin K reductase (*VKORC1*) can also affect susceptibility of the enzyme to warfarin-induced inhibition, thereby influencing warfarin dosage requirements.

TABLE 82-9 Frequencies of *CYP2C9* Genotypes and *VKORC1* Haplotypes in Different Populations and their Effect on Warfarin Dose Requirements

GENOTYPE/ HAPLOTYPE	FREQUENCY (%)			DOSE REDUCTION COMPARED WITH WILD- TYPE (%)

the U.S. Food and Drug Administration to amend the prescribing information for warfarin to recommend lower starting doses for patients with the *CYP2C9* and *VKORC1* genetic variants. In addition to genetic factors, fluctuations in the dietary intake of vitamin K, drugs, and various disease states influence the anticoagulant effect of warfarin. Consequently, computerized genotype-based warfarin-dosing algorithms also include pertinent patient characteristics, such as age, body weight and concomitant medications.⁸⁵ Although these algorithms streamline warfarin dosing, randomized trials following time in therapeutic range with genotype-based warfarin dosing have yielded mixed results. It remains unclear whether better dose identification improves patient outcomes in terms of reducing hemorrhagic complications or recurrent thrombotic events.⁸⁶⁻⁸⁸

MONITORING. Warfarin therapy is most often monitored with the prothrombin time, a test sensitive to reductions in the levels of prothrombin, factor VII, and factor X. The test involves the addition of thromboplastin, a reagent that contains tissue factor, phospholipid, and calcium, to citrated plasma and determination of the time until clot formation. Thromboplastins vary in their sensitivity to reductions in the levels of vitamin K–dependent clotting factors. Consequently, less sensitive thromboplastins will trigger the administration of higher doses of warfarin to achieve a target prothrombin time. This issue can cause problems because higher doses of warfarin increase the risk for bleeding.

The INR was developed to circumvent many of the problems associated with the prothrombin time. To calculate the INR, the patient's prothrombin time is divided by the mean normal prothrombin time, and this ratio is then multiplied by the international sensitivity index (ISI), an index of the sensitivity of the thromboplastin used for determination of the prothrombin time to reductions in levels of the vitamin K–dependent clotting factors. Highly sensitive thromboplastins have an ISI of 1.0. Most current thromboplastins have ISI values that range from 1.0 to 1.4.⁷⁹

Although the INR has helped standardize anticoagulant practice, problems persist. The precision of INR determination varies depending on reagent-coagulometer combinations, which has led to variability in INR results. Unreliable reporting of the ISI by thromboplastin manufacturers also complicates determination of the INR. Furthermore, every laboratory must establish the mean normal prothrombin time with each new batch of thromboplastin reagent. To accomplish this, the prothrombin time must be measured in fresh plasma samples from at least 20 healthy volunteers via the same coagulometer that is used for patient samples.

For most indications, warfarin is administered at doses that produce a target INR of 2.0 to 3.0. An exception is patients with mechanical heart valves in the mitral position, in whom a target INR of 2.5 to 3.5 is recommended. Studies in patients with atrial fibrillation demonstrate an increased risk for cardioembolic stroke when the INR falls below 1.7 and an increase in bleeding with INR values higher than 4.5. These findings highlight the narrow therapeutic window of vitamin K antagonists. In support of this concept, a study in patients receiving long-term warfarin therapy for unprovoked VTE demonstrated a higher rate of recurrent VTE with a target INR of 1.5 to 1.9 than with a target INR of 2.0 to 3.0.

DOSING. Warfarin is usually started at a dose of 5 to 10 mg. Lower doses are used for patients with *CYP2C9* or *VKORC1* polymorphisms that affect the pharmacodynamics or pharmacokinetics of warfarin and render patients more sensitive to the drug. The dose is then titrated to achieve the desired target INR. Because of its delayed onset of action, patients with established thrombosis or those at high risk for thrombosis are given concomitant treatment with a rapidly acting parenteral anticoagulant, such as heparin, LMWH, or fondaparinux. Initial prolongation of the INR reflects a reduction in the functional levels of factor VII. Consequently, concomitant treatment with the parenteral anticoagulant should be continued until the INR has been therapeutic for at least 2 consecutive days. A minimum 5-day course of parenteral anticoagulation is recommended to ensure that the levels of prothrombin have fallen into the therapeutic range with warfarin.

Because warfarin has a narrow therapeutic window, frequent monitoring of coagulation is essential to ensure that the anticoagulant

response is therapeutic. Even patients with stable warfarin dose requirements should have their INR determined every 3 to 4 weeks. Although a recent study has raised the possibility that testing every 12 weeks may be sufficient in such patients, these results require confirmation in a large number of patients.⁸⁹ More frequent INR monitoring is necessary with the introduction of new medications because many drugs enhance or reduce the anticoagulant effects of warfarin.

SIDE EFFECTS. Like all anticoagulants, the major side effect of warfarin is bleeding; a rare complication is skin necrosis. Warfarin crosses the placenta and can cause fetal abnormalities, so it should not be used during pregnancy.

BLEEDING. At least half of the bleeding complications with warfarin occur when the INR exceeds the therapeutic range. Bleeding complications may be mild, such as epistaxis or hematuria, or more severe, such as retroperitoneal or gastrointestinal bleeding. Life-threatening intracranial bleeding can also occur.

To minimize the risk for bleeding, the INR should be maintained in the therapeutic range. In asymptomatic patients whose INR is between 3.5 and 9, warfarin should be withheld until the INR returns to the therapeutic range. If the patient is at high risk for bleeding, sublingual vitamin K can be administered. A vitamin K dose of 1 to 2.5 mg is usually adequate for patients with an INR between 4.9 and 9, whereas 2.5 to 5 mg can be used for those with an INR higher than 9. Higher doses of oral vitamin K (5 to 10 mg) produce more rapid reversal of the INR and may be helpful if the INR is excessively high.

Patients with serious bleeding need additional treatment. These patients require 10 mg of vitamin K by slow intravenous infusion with additional doses of vitamin K until the INR is in the normal range and fresh frozen plasma to replace the vitamin K–dependent clotting proteins. For life-threatening bleeding or if patients cannot tolerate the volume load, prothrombin complex concentrates can be used.⁷⁹

Warfarin-treated patients who experience bleeding when their INR is in the therapeutic range require investigation of the cause of the bleeding. Those with gastrointestinal bleeding often have underlying peptic ulcer disease or a tumor. Similarly, investigation of hematuria or uterine bleeding in patients with a therapeutic INR may unmask a tumor of the genitourinary tract.

SKIN NECROSIS. A rare complication of warfarin, skin necrosis usually occurs 2 to 5 days after initiation of therapy. Well-demarcated erythematous lesions form on the thighs, buttocks, breasts, or toes. Typically, the center of the lesion becomes progressively necrotic. Examination of skin biopsy specimens taken from the borders of these lesions reveals thrombi in the microvasculature.

Warfarin-induced skin necrosis occurs in patients with congenital or acquired deficiencies of protein C or protein S.⁷⁹ Initiation of warfarin therapy in these patients produces a precipitous fall in plasma levels of proteins C or S, thereby eliminating this important anticoagulant pathway before warfarin exerts an antithrombotic effect through lowering the functional levels of factor X and prothrombin. The resultant procoagulant state triggers thrombosis that is localized to the microvasculature of fatty tissues for unknown reasons.

Treatment involves discontinuation of warfarin and reversal with vitamin K, if needed. An alternative anticoagulant, such as heparin or LMWH, should be given to patients with thrombosis. Protein C concentrates may accelerate healing of the skin lesions in protein C–deficient patients; fresh frozen plasma may be of value for those with protein S deficiency. Occasionally, skin grafting is necessary in those with extensive skin loss.

Because of the potential for skin necrosis, patients with known protein C or protein S deficiency require overlapping treatment with a parenteral anticoagulant when initiating warfarin therapy. Warfarin should be started at low doses in these patients, and the parenteral anticoagulant should be continued until the INR is therapeutic for at least 2 to 3 consecutive days.

PREGNANCY. Warfarin crosses the placenta and can cause fetal abnormalities or bleeding. The fetal abnormalities include a characteristic embryopathy, which consists of nasal hypoplasia and stippled epiphyses. The risk for embryopathy is highest with warfarin administration in the first trimester of pregnancy. Central nervous system

abnormalities can also occur with exposure to warfarin at any time during pregnancy. Finally, maternal administration of warfarin produces an anticoagulant effect in the fetus that can cause bleeding. This is of particular concern at delivery, when trauma to the head during passage through the birth canal can lead to intracranial bleeding. Because of these potential problems, warfarin is contraindicated in pregnancy, particularly in the first and third trimesters. Instead, heparin, LMWH, or fondaparinux can be given during pregnancy for prevention or treatment of thrombosis. Warfarin does not pass into breast milk and thus is safe for nursing mothers.

SPECIAL PROBLEMS. Patients with an LA or those who need urgent or elective surgery present special challenges. Observational studies have suggested that patients with thrombosis complicating antiphospholipid syndrome require higher-intensity warfarin regimens to prevent recurrent thromboembolic events, an approach that increases the risk for bleeding. Two randomized trials, however, indicated that usual-intensity warfarin treatment (INR of 2.0 to 3.0) is as effective as higher-intensity therapy and produces less bleeding.^{90,91} Monitoring of warfarin can be problematic in patients with antiphospholipid syndrome if the LA prolongs the baseline INR; factor X levels can be used instead of the INR in such patients.

There is no need to stop warfarin treatment before procedures associated with a low risk for bleeding, including dental cleaning, simple dental extraction, cataract surgery, or skin biopsy. In contrast, warfarin must be stopped 5 days before elective invasive procedures associated with a moderate or high risk for bleeding to allow the INR to return to normal levels. Patients at high risk for thrombosis while not taking warfarin require bridging with once- or twice-daily subcutaneous injections of LMWH when the INR falls below 2.0. The last dose of LMWH should be given 12 to 24 hours before the procedure, depending on whether LMWH is administered twice or once daily, respectively. Once hemostasis is secure after the procedure, warfarin can be restarted.

Direct Oral Anticoagulants

(See also Chapters 52, 53, and 73)

Newer, direct oral anticoagulants that target thrombin or factor Xa are now available as alternatives to warfarin. These drugs have a rapid onset of action and half-lives that permit once- or twice-daily administration. Designed to produce a predictable level of anticoagulation, the new oral agents are more convenient to administer than warfarin because they are given in fixed doses without routine monitoring of coagulation.

Mechanism of Action

The new oral anticoagulants are small molecules that bind reversibly to the active site of their target enzyme. Table 82-10 summarizes the pharmacologic features of these agents.

TABLE 82-10 Comparison of the Features of the New Oral Anticoagulants

FEATURES	RIVAROXABAN	APIXABAN	DABIGATRAN ETEXILATE
Target	Xa	Xa	IIa
Molecular weight	436	460	628
Prodrug	No	No	Yes
Bioavailability (%)	80	50	6
Time to peak (hr)	3	3	2
Half-life (hr)	9	9-14	12-17
Renal excretion (%)	33	25	80
Antidote	None	None	None

Dosing

For prevention of stroke in patients with nonvalvular atrial fibrillation, rivaroxaban is given at a dosage of 20 mg once daily with a reduction to 15 mg once daily in patients with a creatinine clearance of 15 to 49 mL/min, dabigatran is given at a dosage of 150 mg twice daily with a reduction to 75 mg twice daily in those with a creatinine clearance of 15 to 30 mL/min, and apixaban is given at a dosage of 5 mg twice daily with a reduction to 2.5 mg twice daily for patients with a creatinine higher than 1.5 g/dL or for those 80 years or older or who weigh less than 60 kg.

Rivaroxaban is licensed for thromboprophylaxis after elective hip or knee replacement surgery and for the treatment of acute VTE. For thromboprophylaxis, the dose is 10 mg once daily; for treatment of VTE, the drug is started at a dose of 15 mg twice daily for 3 weeks and then reduced to 20 mg once daily thereafter.

Dabigatran is undergoing regulatory review for the treatment of VTE. For this indication, patients must first receive a minimum of a 5-day course of a parenteral anticoagulant before starting dabigatran at a dosage of 150 mg twice daily.

Apixaban is not yet licensed for the treatment of VTE. For the treatment of acute VTE, apixaban is started at a dosage of 10 mg twice daily for 7 days and then reduced to 5 mg twice daily thereafter. This all-oral regimen was shown to be as effective as conventional anticoagulant therapy for the treatment of patients with deep vein thrombosis and/or pulmonary embolism but was associated with a 69% reduction in major bleeding.⁹² For long-term secondary prevention, the dosage of apixaban can be lowered to 2.5 mg twice daily, a dose that has a safety profile similar to that of placebo.⁹³

Edoxaban is at an earlier stage in clinical development. Phase III clinical trials have been completed, and edoxaban is now under regulatory review for prevention of stroke in patients with atrial fibrillation and for treatment of VTE.

Monitoring

Although administered without routine monitoring, in some situations determination of the anticoagulant activity of the new oral anticoagulants can be helpful,⁹⁴ including assessment of adherence, detection of accumulation or overdose, identification of bleeding mechanisms, and determination of activity before surgery or intervention. For qualitative assessment of anticoagulant activity, the prothrombin time can be used for factor Xa inhibitors and the APTT for dabigatran. Rivaroxaban prolongs the prothrombin time more than apixaban does. In fact, because apixaban has such a limited effect on the prothrombin time, anti-factor Xa assays are needed to assess its activity.⁹⁴ The effect of the drugs on tests of coagulation varies depending on the reagents used to perform the tests, and variability increases with conversion of the prothrombin time to an INR. Chromogenic anti-factor Xa assays and a dilute thrombin clotting time with appropriate calibrators provide quantitative assays to measure plasma levels of the factor Xa inhibitors and dabigatran, respectively.⁹⁵

Side Effects

Like any anticoagulant, bleeding is the most common side effect of the new oral anticoagulants. Although the new agents are associated with less intracranial bleeding than warfarin is, the risk for gastrointestinal bleeding is higher with dabigatran and rivaroxaban than with warfarin. Dyspepsia occurs in up to 10% of patients treated with dabigatran; this problem improves with time and can be minimized by taking the drug with food.

Periprocedural Management

Like warfarin, use of the new oral anticoagulants must be stopped before procedures associated with a moderate or high risk for bleeding.⁹⁵ The drugs should be withheld for 1 to 2 days or longer if renal function is impaired. Assessment of residual anticoagulant activity before high-risk procedures is prudent.

Management of Bleeding

The new oral anticoagulants have no specific antidotes. With minor bleeding, withholding one or two doses of drug is usually sufficient.

With more serious bleeding, the approach is similar to that with warfarin except that vitamin K administration is of no benefit; the anticoagulant and any antiplatelet drugs should be withheld, the patient should be resuscitated with fluids and blood products as necessary, and the bleeding site should be identified and managed. Coagulation testing will determine the extent of anticoagulation, and renal function should be assessed so that the half-life of the drug can be calculated. Timing of the last dose of anticoagulant is important, and oral activated charcoal may help prevent absorption of drug administered in the past 4 to 6 hours. If bleeding continues or is life-threatening, procoagulants, such as prothrombin complex concentrates (either unactivated or activated) or factor VIIa, can be administered, although evidence of their effectiveness is limited. Dialysis removes dabigatran from the circulation in patients with renal impairment; it does not remove rivaroxaban or apixaban because unlike dabigatran, they are highly protein bound.⁹⁵

Pregnancy

As small molecules, the new oral anticoagulants can all pass through the placenta. Consequently, these agents are contraindicated in pregnancy, and when used by women of childbearing potential, appropriate contraception is important.

Ongoing Investigations

Although the safety of the new oral anticoagulants has been questioned, postmarketing surveillance data are reassuring. For example, interrogation of the mini-sentinel database reveals that rates of intracranial and gastrointestinal bleeding are lower with dabigatran than with warfarin.⁹⁶ In addition, not only is intracranial hemorrhage less frequent with dabigatran than with warfarin, but the outcome of patients with such bleeding is also similar.⁹⁷ Therefore even though warfarin can be reversed whereas dabigatran cannot, outcomes appear to be the same. Nonetheless, antidotes are under development. A humanized mouse monoclonal antibody fragment against dabigatran is under development as an antidote for dabigatran,⁹⁸ and a recombinant variant of factor Xa is being developed as an antidote for oral factor Xa inhibitors.⁹⁹ These antidotes, however, are probably several years away from approval.

Fibrinolytic Drugs (Also see Chapter 52)

Used to degrade thrombi, fibrinolytic drugs are administered systemically or are delivered via catheters directly into the substance of the thrombus. Currently approved fibrinolytic agents include streptokinase; acylated plasminogen streptokinase activator complex (anistreplase); urokinase; recombinant t-PA (rt-PA), also known as alteplase or activase; and two recombinant derivatives of rt-PA, tenecteplase and reteplase. All these agents act by converting the proenzyme, plasminogen, to plasmin, the active enzyme.¹⁰ There are two pools of plasminogen—circulating plasminogen and fibrin-bound plasminogen (Fig. 82-14). Plasminogen activators that preferentially activate fibrin-bound plasminogen are fibrin specific. In contrast, nonspecific plasminogen activators do not discriminate between fibrin-bound and circulating plasminogen.¹⁰⁰ Activation of circulating plasminogen results in the generation of unopposed plasmin, which can trigger the systemic lytic state. Alteplase and its derivatives are fibrin-specific plasminogen activators, whereas streptokinase, anistreplase, and urokinase are nonspecific agents.

Streptokinase

Unlike other plasminogen activators, streptokinase is not an enzyme and does not directly convert plasminogen to plasmin. Instead, it forms a 1:1 stoichiometric complex with plasminogen, thereby inducing a conformational change in plasminogen that exposes its active site (Fig. 82-15). This conformationally altered plasminogen then converts additional plasminogen molecules to plasmin.¹⁰ Streptokinase has no affinity for fibrin, and the streptokinase-plasminogen complex activates both free and fibrin-bound plasminogen. Activation of circulating plasminogen generates sufficient amounts of plasmin to overwhelm α_2 -antiplasmin. Unopposed plasmin not

FIGURE 82-14 Consequences of activation of fibrin-bound or circulating plasminogen. The fibrin specificity of plasminogen activators reflects their capacity to distinguish between fibrin-bound and circulating plasminogen, which depends on their affinity for fibrin. Plasminogen activators with high affinity for fibrin preferentially activate fibrin-bound plasminogen. This results in the generation of plasmin on the fibrin surface. Fibrin-bound plasmin, which is protected from inactivation by α_2 -antiplasmin, degrades fibrin to yield soluble fibrin degradation products. In contrast, plasminogen activators with little or no affinity for fibrin do not distinguish between fibrin-bound and circulating plasminogen. Activation of circulating plasminogen results in systemic plasminemia and subsequent degradation of fibrinogen and other clotting factors.

FIGURE 82-15 Mechanism of action of streptokinase. Streptokinase binds to plasminogen and induces a conformational change in plasminogen that exposes its active site. The streptokinase/plasminogen complex then serves as the activator of additional plasminogen molecules.

only degrades fibrin in the occlusive thrombus but also induces a systemic lytic state.¹⁰¹

When given systemically to patients with acute myocardial infarction, streptokinase reduces mortality. For this indication the drug is usually administered as an intravenous infusion of 1.5 million units over a period of 30 to 60 minutes. Patients who receive streptokinase can form antibodies against it, as can patients with previous streptococcal infection. These antibodies can reduce the effectiveness of streptokinase.

Allergic reactions occur in approximately 5% of patients treated with streptokinase. They may be manifested as a rash, fever, chills,

and rigors; rarely, anaphylactic reactions can occur. Transient hypotension is common with streptokinase and probably reflects plasmin-mediated release of bradykinin. The hypotension usually responds to leg elevation and administration of intravenous fluids and low doses of vasopressors, such as dopamine or norepinephrine.

Anistreplase

To generate this drug, streptokinase is mixed with equimolar amounts of Lys-plasminogen, a plasmin-cleaved form of plasminogen with a Lys residue at its N-terminal. The active site of Lys-plasminogen exposed on combination with streptokinase is then blocked with an anisoyl group. After intravenous infusion the anisoyl group is slowly removed by deacylation, which yields a half-life of approximately 100 minutes for the complex. This allows drug administration via a single bolus infusion. Although it is more convenient to administer, anistreplase offers few mechanistic advantages over streptokinase. Like streptokinase, anistreplase does not distinguish between fibrin-bound and circulating plasminogen. Consequently, anistreplase produces a systemic lytic state. Similarly, allergic reactions and hypotension are just as frequent with anistreplase as they are with streptokinase.¹⁰²

When anistreplase was compared with alteplase in patients with acute myocardial infarction, reperfusion was achieved more rapidly with alteplase than with anistreplase. Improved reperfusion was associated with a trend toward better clinical outcomes and reduced mortality with alteplase. The modest improvement in outcomes and the high cost of anistreplase have dampened enthusiasm for its use.

Urokinase

Derived from cultured fetal kidney cells, urokinase is a two-chain serine protease with a molecular weight of 34,000.¹⁰³ Urokinase directly converts plasminogen to plasmin. Unlike streptokinase, urokinase is not immunogenic, and allergic reactions are rare. Urokinase produces a systemic lytic state because it does not discriminate between fibrin-bound and circulating plasminogen. Despite many years of use, systemic urokinase has never been evaluated for coronary fibrinolysis; instead, it is used for catheter-directed lysis of thrombi in the deep veins or in coronary or peripheral arteries.

Alteplase

A recombinant form of single-chain t-PA, alteplase has a molecular weight of 68,000. Plasmin rapidly converts alteplase into its two-chain form. The interaction of alteplase with fibrin is mediated by the finger domain and, to a lesser extent, by the second kringle domain (Fig. 82-16).¹⁰ The affinity of alteplase for fibrin is considerably higher than that for fibrinogen. Consequently, the catalytic efficiency of plasminogen activation by alteplase is two to three orders of magnitude higher in the presence of fibrin than in the presence of fibrinogen.¹⁰¹

Although alteplase preferentially activates plasminogen in the presence of fibrin, it is not as fibrin selective as was first predicted. Its fibrin specificity is limited because like fibrin, (DD)E, the major soluble degradation product of cross-linked fibrin, binds alteplase and plasminogen with high affinity. As a result, (DD)E is as potent as fibrin as a stimulator of plasminogen activation by alteplase. Plasmin generated on the fibrin surface results in thrombolysis, whereas plasmin generated on the surface of circulating (DD)E degrades fibrinogen. Fibrinogenolysis results in the accumulation of fragment X, a high-molecular-weight clottable fibrinogen degradation product. Incorporation of fragment X into hemostatic plugs formed at sites of vascular injury renders them susceptible to lysis.¹⁰⁴ This phenomenon may contribute to alteplase-induced bleeding.

A trial comparing alteplase with streptokinase for the treatment of patients with acute myocardial infarction demonstrated significantly lower mortality with alteplase than with streptokinase, although the absolute difference was small. Patients older than 75 years with anterior myocardial infarction who were initially seen less than 6 hours after the onset of symptoms derived the greatest benefit from alteplase. Acute myocardial infarction or acute ischemic stroke is treated with an intravenous infusion of alteplase over a 60- to 90-minute period. The total dose of alteplase usually ranges from 90

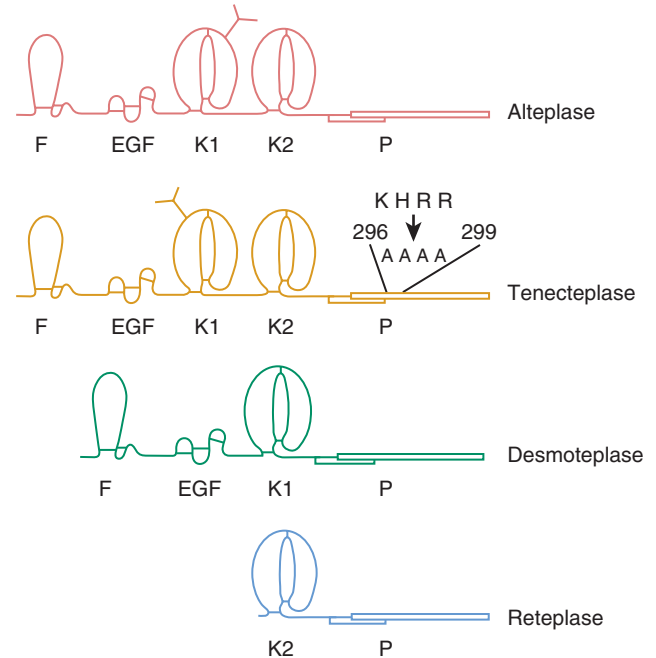

FIGURE 82-16 Domain structures of alteplase, tenecteplase, desmoteplase, and reteplase. (Also see Figure 54-9.) The finger (F), epidermal growth factor (EGF), first and second kringles (K1 and K2, respectively), and protease (P) domains are illustrated. The glycosylation site (Y) on K1 has been repositioned in tenecteplase to endow it with a longer half-life. In addition, a tetra-alanine substitution in the protease domain renders tenecteplase resistant to PAI-1 inhibition. Desmoteplase differs from alteplase and tenecteplase in that it lacks a K2 domain. Reteplase is a truncated variant that lacks the F, EGF, and K1 domains.

to 100 mg. Allergic reactions and hypotension are rare, and alteplase is not immunogenic.

Tenecteplase

A genetically engineered variant of t-PA, tenecteplase was designed to have a longer half-life than t-PA and to be resistant to inactivation by PAI-1.¹⁰⁵ To prolong its half-life, a new glycosylation site was added to the first kringle domain (Fig. 82-16). Because addition of this extra carbohydrate side chain reduced fibrin affinity, the existing glycosylation site on the first kringle domain was removed. To render the molecule resistant to inhibition by PAI-1, a tetra-alanine substitution was introduced at residues 296 to 299 in the protease domain, the region responsible for the interaction of t-PA with PAI-1.

Tenecteplase is more fibrin specific than t-PA. Although both agents bind to fibrin with similar affinity, the affinity of tenecteplase for (DD)E is significantly lower than that of t-PA.¹⁰⁵ Consequently, (DD)E does not stimulate systemic plasminogen activation by tenecteplase to the same extent as t-PA does. As a result, tenecteplase produces less fibrinogenolysis than t-PA does.

For coronary fibrinolysis, tenecteplase is administered as a single intravenous bolus. In a large phase III trial that enrolled more than 16,000 patients, the 30-day mortality rate with single-bolus tenecteplase was similar to that with accelerated-dose t-PA. Although rates of intracranial hemorrhage were also similar with both treatments, patients given tenecteplase had less noncerebral bleeding and a reduced need for blood transfusions in comparison to those treated with t-PA. The improved safety profile of tenecteplase probably reflects its enhanced fibrin specificity.

Reteplase

A recombinant t-PA derivative, reteplase is a single-chain variant that lacks the finger, epidermal growth factor, and first kringle domains (Fig. 82-16). This truncated derivative has a molecular weight of 39,000. Reteplase binds fibrin more weakly than t-PA does because it lacks the finger domain. Because it is produced in *Escherichia coli*,

reteplase is not glycosylated; this endows it with a plasma half-life longer than that of t-PA. Consequently, reteplase is given as two intravenous boluses separated by 30 minutes. Clinical trials have demonstrated that reteplase is at least as effective as streptokinase for the treatment of acute myocardial infarction,¹⁰⁶ but it is not superior to t-PA.

Newer Fibrinolytic Agents

Newer fibrinolytic agents include desmoteplase (Fig. 82-16), a recombinant form of the full-length plasminogen activator isolated from the saliva of the vampire bat,¹⁰⁷ and alteplase, a truncated form of fibrinase, an enzyme isolated from the venom of the southern copperhead snake.¹⁰⁸ Clinical studies with these agents have been disappointing. Desmoteplase, which is more fibrin specific than t-PA, was investigated for the treatment of acute ischemic stroke. Patients initially seen 3 to 9 hours after the onset of symptoms were randomly assigned to one or two doses of desmoteplase or to placebo.¹⁰⁹ Overall response rates were low, and no differences from placebo were noted. Mortality was higher in the desmoteplase arms.

Alteplase is a metalloproteinase that degrades fibrin and fibrinogen in a plasmin-independent fashion.¹¹⁰ In the circulation, alpha₂-macroglobulin inhibits alteplase, so alteplase must be delivered via a catheter directly into the thrombus. Despite promising phase III results,¹¹⁰ studies of alteplase for the treatment of peripheral arterial occlusion or for restoration of flow in blocked central venous catheters were stopped because of lack of efficacy. The disappointing results with desmoteplase and alteplase highlight the challenges of introducing new fibrinolytic drugs.

CONCLUSIONS AND FUTURE DIRECTIONS

Thrombosis in arteries or veins reflects a complex interplay among the vessel wall, platelets, the coagulation system, and the fibrinolytic pathways. Activation of coagulation also triggers inflammatory pathways that may contribute to thrombogenesis. A better understanding of the biochemistry of platelet aggregation and blood coagulation and advances in structure-based drug design have identified new targets and prompted the development of novel antithrombotic drugs. Despite these advances, however, arterial and venous thromboembolic disorders remain a major cause of morbidity and mortality. The search for better targets and more potent, safer, or more convenient antiplatelet, anticoagulant, and fibrinolytic drugs continues.

Rheumatic fever is the leading cause of acquired heart disease in children and young adults worldwide. Initiated by a group A beta-hemolytic streptococcal (GAS) pharyngeal infection and following a latent period of approximately 2 to 3 weeks, the illness is characterized by acute inflammation of the heart, joints, skin, subcutaneous tissue, and central nervous system. Pathologically, the inflammatory process causes damage to collagen fibrils and connective tissue ground substance (i.e., fibrinoid degeneration), and thus rheumatic fever is classified as a connective tissue or collagen-vascular disease.

It is the destructive effect on the heart valves that leads to the chronic sequelae of the disease (i.e., rheumatic heart disease), with serious hemodynamic disturbances causing cardiac failure, as well as other complications such as stroke and infective endocarditis. Referring to the fleeting arthritis and damaging carditis characteristic of rheumatic fever, the French physician Ernst-Charles Lasègue famously said in 1884, “*Pathologists have long known that rheumatic fever licks at the joints, but bites at the heart.*” Almost all cases of rheumatic fever and rheumatic heart disease and associated deaths are entirely preventable.

EPIDEMIOLOGY

The burden of rheumatic fever and rheumatic heart disease has been characterized by at least four changing patterns over the past 150 years (Fig. 83-1). The first pattern represents the preantibiotic fall in the incidence of rheumatic fever that is typical of industrialized countries (curve A, Fig. 83-1). For example, in the United States the incidence per 100,000 was 100 at the start of 20th century, 45 to 65 between 1935 and 1960, and currently estimated to be less than 10 cases per 100,000.¹ The decrease in the incidence of rheumatic fever preceded the introduction of antibiotics in the 1940s and is almost certainly due to improved socioeconomic standards, less overcrowded housing, and improved access to medical care.

The second pattern is characterized by a persistently high incidence of rheumatic fever in developing regions that do not have any comprehensive national programs of primary and secondary prevention (curve B, Fig. 83-1). The incidence of rheumatic fever in Maori children is as high as 59 per 100,000 per year, as compared with 1.1 per 100,000 in the non-Maori community of New Zealand.² This hyperendemic pattern of rheumatic fever affects most of the population of the world who live in Africa, the Middle East, Asia, eastern Europe, South America, and indigenous communities of Australasia.³

Third, some developing countries, such as Cuba, Costa Rica, and the French islands of Martinique and Guadeloupe, have experienced a falling incidence of rheumatic fever following the implementation of comprehensive public health programs for primary and secondary prevention of rheumatic fever (curve C, Fig. 83-1).⁴ By contrast, African countries that have not implemented public health programs

for the prevention of rheumatic fever continue to experience a high incidence of rheumatic fever and rheumatic heart disease.⁵

Outbreaks of rheumatic fever have been reported in affluent communities of the United States and Italy.⁶ The epidemiologic transition in the former Soviet Union has been associated not only with an increase in mortality rates from atherosclerotic diseases and trauma in Russia but also with a sustained resurgence of rheumatic fever and rheumatic heart disease in central Asia.⁷ The incidence of rheumatic fever in central Asia fell to the same levels as those in Japan in the middle 1970s but rose sharply in the post-Soviet period to levels associated with developing countries (curve D, Fig. 83-1). In developing countries, Kyrgyzstan probably has the highest incidence of rheumatic fever and rheumatic heart disease—approximately 543 per 100,000 population per year—thus earning the central Asian republics the dubious distinction of being the rheumatic fever “hot spot” of the world. The resurgence of rheumatic fever in the formerly Soviet republics may reflect weakening of the primary health care system and the economic crisis of the post-Soviet period (see Tulchinsky and colleagues in Classic Reading List).

PATHOGENESIS

Rheumatic fever is a multifactorial disease that follows GAS pharyngitis (the agent) in a susceptible individual (the host) who lives under deprived social conditions (the environment). The theory of molecular mimicry holds that GAS pharyngitis triggers an autoimmune response to epitopes in the organism that cross-react with similar epitopes in the heart, brain, joints, and skin, and repeated episodes of rheumatic fever lead to rheumatic heart disease (Fig. 83-2).⁸

The Agent

Epidemiologic and immunologic observations together with the preventive effect of antibiotic treatment of pharyngitis demonstrated in clinical trials strongly support the causative role of untreated GAS pharyngitis in rheumatic fever.⁹ Streptococcal skin infection is not thought to cause rheumatic fever. However, a report of rheumatic fever following streptococcal wound infection and the high prevalence of pyoderma with a relative paucity of streptococcal pharyngitis in aboriginal communities of Australasia with a high incidence of rheumatic fever has raised questions about the link between streptococcal skin infection and rheumatic fever.¹⁰ Although effective antibiotic treatment substantially reduces the risk for rheumatic fever, in situations of untreated epidemic GAS pharyngitis, the disease develops in up to 3% of patients.¹¹

Cunningham reviewed the hypothesis of molecular mimicry in the pathogenesis of rheumatic fever.⁹ There is evidence that patients with rheumatic heart disease have cross-reactive autoantibodies that target the dominant GAS epitope of the group A carbohydrate *N*-acetyl-beta-D-glucosamine (GlcNAc), as well as laminin and the laminar basement membrane in heart valve endothelium. T cells in peripheral

blood and heart valves of patients with rheumatic heart disease cross-react with streptococcal M protein and cardiac myosin. Furthermore, autoantibodies against the GAS carbohydrate epitope GlcNAc and cardiac myosin appear during progression of rheumatic heart disease. In addition, autoantibodies against collagen that are not cross-reactive may form because of the release of collagen from damaged valves.

The two-hit hypothesis for initiation of disease proposes that attack of valve endothelium by antibody facilitates extravasation of T cells through activated epithelium into valve tissue and thereby leads to formation of the granulomatous nodules called Aschoff bodies that are characteristic of rheumatic myocarditis. The area of central necrosis is surrounded by a ring of plump histiocytes called Anitschkov cells (Fig. 83-3). These nodules were discovered independently by Ludwig Aschoff and Paul Rudolf Geipel, and for this reason they are occasionally called Aschoff-Geipel bodies.

In Sydenham chorea, human monoclonal antibodies derived from patients with disease target GlcNAc, gangliosides, and dopamine receptors found on the surface of neuronal cells in the brain. Human monoclonal antibodies and autoantibodies in Sydenham chorea activate calcium/calmodulin-dependent protein kinase II (CaMKII) in neuronal cells and recognize the intracellular protein biomarker tubulin. Therefore the theme of molecular mimicry in rheumatic fever is characterized by recognition of targeted intracellular biomarker antigens (i.e., cardiac myosin and brain tubulin) while targeting extracellular membrane antigens (i.e., laminin on the endothelial surface of the valve or lyso-ganglioside and dopamine receptors in the brain).⁹

The Host

Several lines of epidemiologic evidence support the role of hereditary factors in susceptibility to rheumatic fever. First, the lifetime cumulative incidence of rheumatic fever in populations exposed to rheumatogenic GAS infection is constant at 3% to 6% regardless of geography or ethnicity.¹² This suggests that the proportion of susceptible individuals is the same in all continental populations of the world.¹³ Second, familial aggregation of rheumatic fever was described by Cheadle as far back as 1889.¹³ Cheadle reported that the chance of an individual with a family history of rheumatic fever acquiring the disease is “nearly 5 times as great as that of an individual who has no such hereditary taint.” The familial aggregation of rheumatic heart disease has been supported by a study of children raised separately from parents with rheumatic heart disease; such children had a relative risk of 2.93 for the development of rheumatic fever in comparison to children whose parents did not have rheumatic heart disease.¹³ Finally, a study of 435 monozygotic twin pairs showed that the risk for rheumatic fever in one twin when the other twin previously had rheumatic fever is increased by more than six times in comparison to that of dizygotic twins. The heritability of rheumatic fever is 60%, which highlights the importance of heredity as a major susceptibility factor for the disease.¹⁴

Numerous studies have been conducted to search for specific genetic susceptibility factors in rheumatic fever.¹⁵ Several genes controlling the adaptive immune response (e.g., HLA class II alleles and

FIGURE 83-1 The four patterns of the incidence of rheumatic fever over the past 150 years. Curve A represents the preantibiotic fall in the incidence of rheumatic fever that is typical of industrialized countries. Curve B is typical of the persistent high incidence of rheumatic fever in regions of the world with no comprehensive program for prevention, such as Africa and south Asia. Curve C shows the postantibiotic fall in the incidence of rheumatic fever in countries that instituted comprehensive programs for primary and secondary prevention of rheumatic fever, such as Cuba, Costa Rica, Martinique, and Guadeloupe. Curve D shows the fall and rise in the incidence of rheumatic fever in the formerly Soviet Republics of Central Asia. (Modified from Parry E, Godfrey R, Mabey D, Gill G [eds]: *Principles of Medicine in Africa*. 3rd ed. Cambridge, Cambridge University Press, 2004, p 861.)

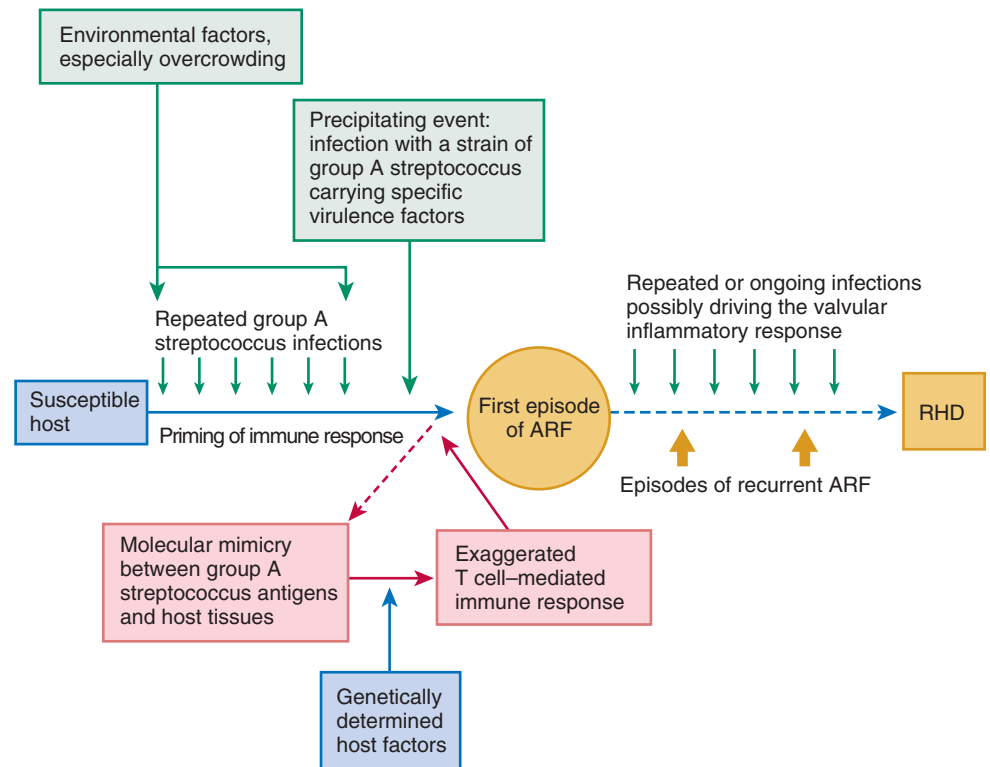

FIGURE 83-2 Pathogenesis of acute rheumatic fever (ARF) and rheumatic heart disease (RHD). (From Carapetis J, McDonald M, Wilson NJ: *Acute rheumatic fever*. *Lancet* 366:155, 2005.)

cytotoxic T cell lymphocyte antigen 4), the innate immune response (e.g., ficolin 2, mannose-binding lectin 2, receptor for the Fc fragments of immunoglobulin G, and toll-like receptor 2), cytokine genes (e.g., tumor necrosis factor- α , transforming growth factor- β , interleukin-1 receptor A, and interleukin-10), and B cell alloantigens have been implicated in development of the disease. Although significant associations have been found between genetic factors and rheumatic fever, study results either conflict with each other or have not been replicated.¹³ Therefore it is not possible at present to predict individuals at risk for the development of rheumatic fever following an episode of untreated streptococcal pharyngitis.

FIGURE 83-3 The Aschoff body of rheumatic fever. Photomicrograph of an Aschoff nodule from the heart in a case of acute rheumatic fever. The nodule is composed of Anitschkow cells; these have clear nuclei with a central bar of chromatin, said to resemble a caterpillar. There is a central area of fibrin. This central necrosis is further surrounded by a mononuclear cell infiltrate. Myocardial fibres adjacent to the Aschoff body are undergoing destruction. (From Sebire NJ, Ashworth M, Malone M, Jacques TS [eds]: *Diagnostic Pediatric Surgical Pathology*. Churchill Livingstone, United Kingdom, 2010.)

The Environment

It is well known that rheumatic fever is generally associated with low socioeconomic status. The incidence of rheumatic fever has been falling consistently in industrialized countries since the mid-19th century, independently of the advent of penicillin, possibly because of less crowding, improved housing and nutritional conditions, higher levels of parental employment, and better access to health care (curve A, Fig. 83-1). In New Zealand, the risk for rheumatic fever has been linked to high levels of deprivation based on household income, access to telephone and car, education level, and housing.¹⁶ The impact of the social gradient has also been illustrated in Uganda, where the increased risk for rheumatic heart disease is associated with overcrowding and unemployment. Furthermore, there was an interaction between overcrowding and distance from the nearest health center, thus suggesting that the effect of overcrowding on the risk of acquiring rheumatic heart disease increases with every increase in kilometer from the nearest health center.¹⁷ In addition, schoolchildren of lower socioeconomic status have been found to have a higher prevalence and more advanced disease in an echocardiographic screening study of rheumatic heart disease in the same country.¹⁸

CLINICAL FEATURES

The typical attack of rheumatic fever follows an episode of streptococcal pharyngitis after a latent period of 2 to 3 weeks. During the latent period there is no clinical or laboratory evidence of active inflammation. However, in as many as a third of patients in whom rheumatic fever develops, it does so after an asymptomatic GAS infection, and in outbreaks, up to 58% of patients have no symptoms of pharyngitis. This is one of the potential barriers to the effectiveness of primary prevention of rheumatic fever solely with antibiotic treatment of GAS pharyngitis and provides justification for the development of an anti-GAS vaccine as one of the strategies for control of rheumatic fever and other streptococcal diseases.

Rheumatic fever occurs most commonly in children between the ages of 4

and 9 years. In developing countries such as Saudi Arabia and India, juvenile mitral stenosis may occur at the age of 3 to 5 years.¹⁹ The prevalence of the various clinical features varies in different studies depending on whether the patients are studied prospectively or in retrospect. The illness usually begins with a high fever, but in some patients the fever may be low grade or absent. The most common of the major criteria is polyarthritis, which occurs in two thirds to three quarters of patients, followed by carditis and chorea.

Arthritis

Joint involvement is more common (almost 100%) and more severe in young adults than in teenagers (82%) and children (66%).²⁰ The joint pain is typically described as migratory, which refers to the sequential involvement of joints, with inflammation resolving in one joint and then beginning in another. Sometimes the joint involvement may be additive rather than migratory, with simultaneous involvement of several joints. In untreated patients the number of joints involved may vary from 6 to 16.²⁰

The affected joint may be inflamed for only a few days to a week before the inflammation subsides. In approximately two thirds of patients, the polyarthritis is severe for around a week and may last another 1 to 2 weeks in the remainder before it resolves completely. If joint swelling persists after 4 weeks, it is necessary to consider other conditions such as juvenile idiopathic arthritis or systemic lupus erythematosus.²⁰

At the onset of the illness, joint involvement is asymmetric, with the lower limbs generally being affected initially before spreading to the upper limbs. Monarthritis has been reported in 17% to 25% of patients.²¹ Large joints such as the knees, ankles, elbows, and wrists are involved most frequently. The hip, shoulder, and small joints of the hands and feet are involved less frequently. Analysis of synovial fluid has shown the presence of sterile inflammatory fluid. There may be a reduction in complement components C1q, C3, and C4, thus suggesting their consumption by immune complexes. Radiographs may show features of a joint effusion, but no other abnormalities are noted.²⁰

Jaccoud arthritis or arthropathy (or chronic post-rheumatic fever arthropathy) is a rare manifestation of rheumatic fever characterized by deformities of the fingers and toes (Fig. 83-4). The condition may occur after repeated attacks of rheumatic fever and results from recurrent inflammation of the fibrous articular capsule. There is ulnar deviation of the fingers, especially the fourth and fifth fingers, flexion of the metacarpophalangeal joints, and hyperextension of the proximal interphalangeal joints (i.e., swan neck deformity). The hand is usually painless without any signs of inflammation. The deformities are generally correctible but may become fixed in the later stages. No true erosions are seen on radiographs, and rheumatoid factor is usually negative. A similar form of arthropathy is seen in patients with systemic lupus erythematosus.²⁰

FIGURE 83-4 Post-rheumatic fever Jaccoud arthropathy. **A**, Swan neck deformity in Jaccoud arthropathy, with ulnar deviation and metacarpophalangeal subluxation. **B**, Plain radiograph of the left hand showing deformities but not erosions. (From Santiago MB: Jaccoud's arthropathy. *Best Prac Res Clin Rheumatol* 25:715, 2011.)

The arthritis of rheumatic fever responds promptly to nonsteroidal anti-inflammatory drugs, and thus the classic finding of migratory polyarthritis may be infrequent at places in which self-medication with anti-inflammatories or their prescription without considering the diagnosis is common. The apparent fall in the incidence of rheumatic fever in some developing countries may be related to the indiscriminate use of nonsteroidal anti-inflammatory drugs without considering a diagnosis of rheumatic fever.²² The differential diagnosis of polyarticular arthritis in children and adolescents includes poststreptococcal reactive arthritis, other autoimmune diseases, septic arthritis, infective endocarditis, Lyme disease, lymphoma/leukemia, viral arthropathy, and sickle cell disease.

Poststreptococcal reactive arthritis is diagnosed in patients who have an arthritis that is not typical of rheumatic fever but who have evidence of recent streptococcal infection. This condition is said to develop after a shorter latent period than occurs with rheumatic fever, responds less well to anti-inflammatories, and may be associated with renal manifestations; evidence of carditis is not usually seen. The distinction between poststreptococcal reactive arthritis and rheumatic fever is unclear, and many would recommend that a diagnosis of poststreptococcal reactive arthritis not be made in populations in which rheumatic fever is common. Even if the diagnosis is considered, it is appropriate to offer a period of secondary penicillin prophylaxis as for episodes of acute rheumatic fever in such populations.²³

Carditis

Carditis is the most serious manifestation of rheumatic fever in that it may lead to chronic rheumatic heart disease with its attendant complications of atrial fibrillation, stroke, heart failure, infective endocarditis, and death. In some cases the carditis may be asymptomatic and is detected during clinical examination of a patient with arthritis or chorea. The incidence of carditis during the initial attack of rheumatic fever varies from 40% to 91%, depending on the selection of patients and whether the diagnosis is made by clinical assessment alone or combined with echocardiography.²³

The incidence of carditis complicating rheumatic fever varies with the age of the patient. It is reported in 90% to 92% of children younger than 3 years, in 50% of children 3 to 6 years of age, in 32% of teenagers aged 14 to 17 years, and in only 15% of adults with a first attack of rheumatic fever.²⁰ In Bland and Jones' review of 1000 patients in 1951, carditis was diagnosed in 65%, and in a report of a Utah outbreak in the United States by Veasy and coauthors, 91% had carditis when clinical examination was combined with echocardiography (see Classic Reading List).

The symptoms and signs of carditis depend on whether the pericardium, myocardium, or heart valves are involved. Clinical diagnosis of carditis is based on detection of an organic murmur that was not previously present (to indicate endocarditis), the presence of a pericardial friction rub or signs of pericardial effusion (to indicate pericarditis), or the presence of cardiomegaly or congestive heart failure (to indicate myocarditis).

Myocarditis in the absence of valvulitis is unlikely to be rheumatic in origin. It should be accompanied by an apical systolic or basal

diastolic murmur. Cardiomegaly and congestive heart failure may develop in patients with myocarditis and may be severe and life-threatening. Myocardial damage may be manifested by electrocardiographic changes, which include varying degrees of heart block. Patients with first-degree heart block are usually asymptomatic. Patients with second- and third-degree heart block may be symptomatic and require a pacemaker if congestive heart failure develops.²⁰ Congestive heart failure may be due to myocarditis or severe involvement of one or more heart valves. It occurs in 5% to 10% of the initial episodes and is more frequent during recurrences of rheumatic fever.

Pericarditis is associated with anterior chest pain, and a pericardial friction rub may be detected on clinical examination. Pericarditis can be detected clinically in approximately 10% of patients. The pericardial effusion may sometimes be large, but cardiac tamponade is rare and constrictive pericarditis does not occur.

The most common valvular lesion is mitral regurgitation causing an apical pansystolic murmur. Aortic regurgitation occurs less frequently. Stenotic lesions are uncommon in the early stages of the disease, but a transient apical mid-diastolic murmur (Carey-Coombs) may occur in association with the murmur of mitral regurgitation. In patients with a previous history of rheumatic heart disease, a change in the character of the murmurs or the appearance of a new murmur will indicate the presence of acute rheumatic carditis.

Because echocardiography is more sensitive and specific than cardiac auscultation for detection of acute rheumatic carditis, it is recommended that all patients with suspected or definite rheumatic fever undergo echocardiography.²⁴ The minimum echocardiographic criteria of the World Heart Federation for the diagnosis of pathologic regurgitation secondary to rheumatic valvulitis are outlined in [Table 83-1](#).²⁵ The advent of portable echocardiography has increased the availability of cardiac ultrasound to many people in developing countries, which has resulted in ultrasound increasingly being used to screen for subclinical rheumatic heart valve disease.

Sydenham Chorea

Chorea may be the only initial manifestation of rheumatic fever. It is more common in females, and after puberty the female preponderance is even greater. The latent period between the episode of streptococcal pharyngitis and the development of chorea is considerably longer (6 to 8 weeks) than that for arthritis and carditis. Chorea is characterized by the presence of involuntary, purposeless, jerky movements of the hands, arms, shoulders, feet, legs, face, and trunk along with hypotonia and weakness. The purposeless movements interfere with voluntary activity and disappear during sleep. Initially, chorea may be confined to the face or one arm, and sometimes it may be completely unilateral (hemichorea).

Patients also show motor impersistence by intermittently, involuntarily withdrawing the tongue when attempting to protrude it for 30 seconds (jack-in-the-box tongue). Motor impersistence may also be demonstrated by asking the patient to squeeze the examiner's hand. This results in repetitive irregular squeezes labeled as "the milking sign." Emotional lability is manifested as changes in personality with inappropriate behavior, restlessness, outbursts of anger or crying, and learning difficulties.

The chorea may last for a week to 2 years but generally persists for 8 to 15 weeks. When chorea occurs alone, the erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and streptococcal antibody

TABLE 83-1 World Heart Federation Minimum Echocardiographic Criteria for the Diagnosis of Pathologic Valvular Regurgitation Secondary to Rheumatic Carditis

PATHOLOGIC MITRAL REGURGITATION (ALL FOUR DOPPLER CRITERIA MUST BE MET)	PATHOLOGIC AORTIC REGURGITATION (ALL FOUR DOPPLER CRITERIA MUST BE MET)
1. Seen on 2 views	1. Seen on 2 views
2. On at least 1 view jet length is ≥ 2 cm*	2. On at least 1 view jet length is ≥ 1 cm*
3. Peak velocity ≥ 3 meters/sec	3. Peak velocity ≥ 3 meters/sec
4. Pansystolic jet in at least 1 envelope	4. Pandsystolic jet in at least 1 envelope

*A regurgitant jet length should be measured from the vena contracta to the last pixel of regurgitant color (blue or red) on nonmagnified (nonzoomed) images.

titers may be normal because of the long latent period and resolution of the original infection. Chorea does not occur simultaneously with arthritis but may coexist with carditis. Some patients with chorea may have a cardiac murmur, whereas others may only later manifest involvement of the mitral valve.

There may be an overlap between Sydenham chorea with motor tics and the involuntary jerks of Tourette syndrome. The term “pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections” (PANDAS) has been used for a subgroup of children with tic or obsessive-compulsive disorders that are triggered by GAS infection with no associated cardiac valve damage.²⁶ However, evidence supporting the existence of PANDAS as a distinct clinical entity has been questioned, which has led to the recommendation that in populations at high risk for rheumatic fever, clinicians should rarely, if ever, make a diagnosis of PANDAS and should rather err on the side of diagnosis of rheumatic fever and implement secondary prophylaxis.²⁴

Subcutaneous Nodules

The subcutaneous nodules of rheumatic fever resemble those of rheumatoid arthritis and may be detected over the occiput, elbows, knees, ankles, and Achilles tendons. In rheumatic fever, the nodules around the elbow tend to occur over the olecranon, whereas rheumatoid nodules tend to occur more distally along the extensor aspect of the upper part of the forearm. They are usually firm, painless, and freely movable over the subcutaneous tissue. The nodules vary in size from 0.5 to 2 cm and tend to occur in crops (Fig. 83-5). They are usually smaller, more discrete, and less persistent than rheumatoid nodules. They were detected in only 1.5% of a series of 786 patients, but a higher prevalence has been reported in earlier studies.²⁰ Nodules are generally seen in children with prolonged active carditis rather than in the early stages of rheumatic fever. They may persist for a few weeks but seldom more than a month. Multiple crops of nodules may be related to the severity of the rheumatic carditis.

Erythema Marginatum

Erythema marginatum is a less common manifestation of rheumatic fever and occurs on the upper part of the arms or trunk but not on the face (Fig. 83-6). It has a characteristic appearance and is therefore helpful in the diagnosis of rheumatic fever, but it is not pathognomonic of the disease. The rash is evanescent, pink, and nonpruritic. It extends centrifugally whereas the skin at the center returns to normal—hence the name “erythema marginatum.” It has an irregular serpiginous border. The rash may also become more prominent after a hot shower. Erythema marginatum generally occurs only in patients with carditis and may develop early or later in the course of the disease.

FIGURE 83-5 Subcutaneous nodules of rheumatic fever over the bony prominences of the elbow. (From Beerman, LB, Kreutzer J, Allada V: *Cardiology*. In: Zitelli BJ, McIntire SC, Nowalk AJ [eds]. *Atlas of Pediatric Physical Diagnosis*. 6th ed. Philadelphia, Saunders, 2012.)

Other Manifestations

The temperature is usually raised during attacks of rheumatic fever and ranges from 38.4°C to 40°C. However, a cutoff value of higher than 37.5°C when temperature is used as a minor diagnostic criterion would allow the diagnosis of fever to be made in 90% of suspected cases of rheumatic fever in endemic communities such as indigenous Australians. The temperature usually decreases within a week and rarely lasts more than 4 weeks.

Abdominal pain may be severe and mimic acute appendicitis. Epistaxis was reported as a common manifestation in the past but is now uncommon. A rapid sleeping pulse rate, tachycardia out of proportion to the fever, malaise, and anemia may be noted in patients with acute rheumatic fever. Rheumatic pneumonia is uncommon and difficult to distinguish from pulmonary edema and other causes of alveolitis.

DIAGNOSIS

Even though no specific clinical, laboratory, or other test can be used to conclusively confirm a diagnosis of rheumatic fever, the diagnosis is generally made by using the clinical criteria first formulated in 1944 by T. Duckett Jones and modified by the World Health Organization (WHO) in 2001 (Table 83-2).²⁷ The diagnosis is suggested if in the presence of a preceding GAS infection two major criteria (carditis, chorea, polyarthritis, erythema marginatum, and subcutaneous nodules) or one major and two minor criteria (fever, arthralgia, elevated ESR, elevated CRP, or a prolonged PR interval on the electrocardiogram) are present. Evidence of a preceding GAS infection, essential for the diagnosis, may be obtained from throat swab culture (positive in only ≈11% of patients at the time of diagnosis of rheumatic fever) or by demonstrating a rising titer of antistreptococcal antibodies, either antistreptolysin O or anti-deoxyribonuclease B.²⁸

There has been concern that strict application of the Jones criteria may result in underdiagnosis of rheumatic fever in endemic areas, particularly in the case of recurrent episodes.²⁴ During recurrence of rheumatic activity in a patient with preexisting rheumatic heart disease, the carditis may precipitate heart failure but may not be possible to diagnose because of lack of information on previous cardiac findings or because valve replacement surgery has been performed. The new WHO criteria thus recommend that a diagnosis of recurrence of rheumatic fever in a patient with preexisting rheumatic heart disease is possible on the basis of minor manifestations and evidence of recent streptococcal infection (Table 83-2).²⁷ The addition of monoarthritis as a major criterion and the inclusion of a temperature higher than 37.5°C as a minor criterion has increased the sensitivity of the modified Jones criteria in communities with

FIGURE 83-6 Erythema marginatum in acute rheumatic fever. The pen mark shows the location of the rash approximately 60 minutes previously. (From Cohen J, Powderly WG: *Infectious Diseases*. 2nd ed. New York, Mosby, 2004.)

TABLE 83-2 World Health Organization Criteria for the Diagnosis of Rheumatic Fever

DIAGNOSTIC CATEGORIES	CRITERIA
1. Primary episode of rheumatic fever	Two major* or one major and two minor† manifestations <i>plus</i> evidence of a preceding GAS infection‡
2. Recurrent attack of rheumatic fever in a patient <i>without</i> established rheumatic heart disease	As for a primary episode of rheumatic fever
3. Recurrent attack of rheumatic fever in a patient <i>with</i> established rheumatic heart disease	Two minor manifestations <i>plus</i> evidence of a preceding GAS infection
4. Rheumatic chorea	Other major manifestations or evidence of GAS infection are <i>not</i> required because these are delayed manifestations of streptococcal infection
5. Insidious-onset rheumatic carditis	
6. Chronic valve lesions of rheumatic heart disease, i.e., patients seen for the first time with pure mitral stenosis or mixed mitral valve disease with or without aortic valve disease	Do <i>not</i> require any other criteria for a diagnosis of rheumatic heart disease

*Major manifestations: carditis, polyarthritis, chorea, erythema marginatum, and subcutaneous nodules.

†Minor manifestations: clinical—fever, polyarthralgia; electrocardiographic—prolonged PR interval; laboratory—elevated acute-phase reactants (ESR, white blood cell count, or CRP).

‡Supporting evidence of a preceding streptococcal infection within the last 45 days: elevated or rising antistreptolysin O or other streptococcal antibody, a positive throat culture or rapid antigen test for group A streptococci, or recent scarlet fever.

From WHO Technical Report Series No. 923. *Rheumatic Fever and Rheumatic Heart Disease: Report of a WHO Expert Panel, Geneva 29 October-1 November 2001. Geneva, WHO, 2004.*

TABLE 83-3 Investigations for Suspected Rheumatic Fever

Recommended for All Cases
White blood cell count
ESR or CRP
Throat swab before giving antibiotics for GAS culture
Blood culture if febrile
Antistreptococcal serology: both antistreptolysin O and anti-DNase B titers (repeated after 10-14 days if the first test is not confirmatory)
Electrocardiogram
Chest radiograph
Echocardiogram
Tests for Alternative Diagnoses, Depending on Clinical Features
Repeated blood cultures with temperature spikes if infective endocarditis is suspected
Joint aspiration for possible septic arthritis (microscopy and culture)
Copper, ceruloplasmin, antinuclear antibody, and drug screen for choreiform movements
Serology and autoimmune markers for arboviral, autoimmune, or reactive arthritis
Peripheral blood smear for sickle cell disease

From RHD Australia (ARF/RHD writing group), National Heart Foundation of Australia and the Cardiac Society of Australia and New Zealand: *Australian Guideline for Prevention, Diagnosis and Management of Acute Rheumatic Fever and Rheumatic Heart Disease*. 2nd ed. Darwin, Australia, Menzies School of Health Research, 2012.

hyperendemic levels of rheumatic fever.²⁴ Physicians should recognize that the published criteria are guidelines and are particularly useful in epidemiologic investigations, where diagnostic rigor is essential. It is appropriate for clinical judgment to be applied and to supersede the guidelines, particularly in parts of the world where rheumatic fever remains common.²³ Investigations recommended for a patient suspected of having rheumatic fever are listed in **Table 83-3**.²⁴

TREATMENT

The aim of treatment of a proven attack of rheumatic fever is to suppress the inflammatory response and therefore minimize the effects of inflammation on the heart and joints, to eradicate GAS organisms from the pharynx, to provide symptomatic relief, and to commence secondary prophylaxis.

The longstanding recommendation of bed rest would appear to be appropriate mainly to lessen joint pain. The duration of bed rest should be determined on an individual basis, but ambulation can usually be started once the fever has subsided and acute-phase reactants are returning toward normal. Strenuous exertion should be avoided, especially in those with carditis.

Even though throat swabs taken during an acute attack of rheumatic fever are rarely positive for GAS organisms, it is advisable for patients to receive an intramuscular dose of benzathine benzylpenicillin (or erythromycin if allergic to penicillin). Although conventional, this strategy is untested. Thereafter, secondary prophylaxis should be commenced.²⁹

The choice of anti-inflammatory agent is between salicylates, non-steroidal anti-inflammatory agents, and corticosteroids. A systematic review of randomized controlled trials comparing anti-inflammatory agents (e.g., aspirin, steroids, immunoglobulins, pentoxifylline) with placebo or controls or comparing any of the anti-inflammatory agents with one another in adults and children with rheumatic fever diagnosed according to the Jones or modified Jones criteria has been published.²⁸ The presence of cardiac disease 1 year after treatment was the major outcome criterion selected. Eight randomized controlled trials involving 996 people were included. Several steroidal agents (i.e., corticotropin, cortisone, hydrocortisone, dexamethasone, and prednisone) and intravenous immunoglobulin were compared with aspirin, placebo, or no treatment in the various studies. Six of the trials were conducted between 1950 and 1965, one study was done in 1990, and the final study was published in 2001. Overall, no significant difference in the risk for cardiac disease was noted at 1 year between the corticosteroid- and aspirin-treated groups (six studies, 907 participants; relative risk, 0.87; 95% confidence interval, 0.66 to 1.15). Similarly, use of prednisone (two studies, 212 participants; relative risk, 1.13; 95% confidence interval, 0.52 to 2.45) versus aspirin did not reduce the risk for the development of heart disease after 1 year. The three studies that provided information on adverse events all reported substantial adverse events. Thus there is little evidence of benefit from the use of corticosteroids or intravenous immunoglobulin in reducing the risk for heart valve lesions in patients with acute rheumatic fever.²⁸

These trials may be criticized on at least two grounds. First, the method used to assess cardiac involvement was clinical, with the development or persistence of an apical systolic murmur being the usual criterion. It could be argued that observer error and interobserver variability in clinical methodology could invalidate the results and that the question should be reexamined by using modern

noninvasive techniques such as echocardiography. It has, however, been shown that at least during the acute phase of the illness, trans-thoracic two-dimensional echocardiography with color flow imaging does not add significantly to clinical evaluation of the degree of cardiac involvement. The second point relates to the duration of follow-up. Lack of clinical evidence of cardiac involvement at 1 or 2 years following the initial attack of acute rheumatic fever is no guarantee that the important sequelae of valvular incompetence or stenosis will not develop in the ensuing decades.

Appropriate dosages of anti-inflammatory agents are 100 mg/kg/day in four or five divided doses for aspirin or 1 to 2 mg/kg/day for prednisone. The duration of therapy must be gauged from the severity of the attack, the presence of carditis, and the rate of response to treatment. Milder attacks with little or no carditis may be treated with salicylates for approximately 1 month or until the inflammation has subsided, as assessed by clinical and laboratory evidence. More severe cases may require 2 to 3 months of steroid therapy before it can be gradually weaned. Up to 5% of patients may still have rheumatic activity despite treatment at 6 months. Occasionally a "rebound" of inflammatory activity can occur when the anti-inflammatory therapy is reduced and may require salicylate treatment.

Patients whose initial attack of rheumatic fever is treated inadequately have a high risk that the rheumatic activity will continue and result in valvular incompetence, most commonly involving the mitral valve. The end result of an ongoing rheumatic process with deteriorating valvular function is heart failure. Experience has shown that in such cases, prompt surgical management is the sole option and can result in the survival of up to 90% of patients.³⁰ It has been suggested that the reduction in cardiac workload following valve surgery results in settling of the rheumatic process—akin to the beneficial effect observed with bed rest.³¹

PREVENTION

There are three levels of prevention of rheumatic fever: primordial prevention, which is based on removal of the social determinants of risk for rheumatic fever; primary prevention of the initial attack; and secondary prevention of recurrent attacks.

Primordial Prevention

Primordial prevention consists of measures to minimize future hazards to health and hence inhibit the establishment of factors (environmental, economic, social, behavioral, cultural) known to increase the risk for disease. It addresses broad health determinants rather than preventing personal exposure to risk factors, which is the goal of primary prevention. In the case of rheumatic fever, improvement of social conditions and increasing access to primary health care have been associated with a dramatic fall in the incidence of the disease even before the discovery of antibiotics (curve A, Fig. 83-1). Therefore prevention of rheumatic fever primarily requires improvement of the socioeconomic status of people at high risk for the development of rheumatic fever.

Primary Prevention

Antibiotic treatment of proven or presumed GAS pharyngitis is effective in reducing the attack rate of rheumatic fever by 70%. Intramuscular penicillin appears to reduce the attack rate by as much as 80%. There is one fewer case of rheumatic fever for every 50 to 60 patients treated with antibiotics.¹¹ The drug regimen of choice is presented in Table 83-4.²⁷

Treatment of proven or presumed GAS pharyngitis is directed toward eradication of the bacteria from the upper respiratory tract. The infection can usually be eradicated by a single intramuscular injection of benzathine benzylpenicillin or by 10 days' treatment with oral penicillin.¹¹ Although the use of intramuscular penicillin to prevent rheumatic fever is supported by clinical trials, few trials have been conducted to test the efficacy of oral penicillin for the primary

TABLE 83-4 Drug Regimen of Choice for the Primary Prevention of Rheumatic Fever

ANTIBIOTIC	ADMINISTRATION	DOSE
Benzathine benzylpenicillin	Single IM injection	1.2 million units; 50% if <30 kg
Phenoxymethylpenicillin (penicillin VK)	PO for 10 days	250-500 mg tid for 10 days
Erythromycin ethylsuccinate	PO for 10 days	Varies with the formulation

IM = intramuscular; PO = per os (by mouth); tid = three times per day.

From WHO Technical Report Series No. 923. Rheumatic Fever and Rheumatic Heart Disease: Report of a WHO Expert Panel, Geneva 29 October-1 November 2001. Geneva, WHO, 2004.

prevention of rheumatic fever. However, there is resistance to using intramuscular penicillin in some developing countries because of the perceived higher risk for anaphylaxis and the danger associated with the potential reuse of needles. Concerns over the safety of intramuscular penicillin have resulted in government orders prohibiting injections of penicillin in hospitals and clinics. Government regulations in response to some of these fears are warranted, particularly in the area of infection control by preventing reuse of needles. However, with respect to the dangers of anaphylaxis, more than 60 years of experience with penicillin has shown that even though toxic reactions to intramuscular penicillin have been reported, severe reactions are exceedingly rare, especially in children. Therefore when given under sterile conditions with an appropriate injection technique, fear regarding the use of parenteral penicillin is unwarranted.¹¹

There are several controversies in the field of primary prevention of rheumatic fever. The first concerns the role of active ascertainment of cases of sore throat in school-based primary prevention programs. This strategy has been tested in a cluster randomized trial of 53 schools (approximately 22,000 students) from a high-incidence rheumatic fever setting (≈60 per 100,000 per year) in Auckland, New Zealand.³² The control group received routine general practice care. The intervention was a school-based sore throat clinic program with free nurse-observed oral penicillin treatment of GAS pharyngitis. This study, which involved 86,874 person-years, showed no significant reduction of rheumatic fever in the school-based sore throat clinic programs.

The second controversy relates to the usefulness of primary prevention as a public health measure for the prevention of rheumatic fever.⁴ Despite the absence of randomized controlled trials of this strategy, there are several examples of successful application of primary prevention in the context of a comprehensive public health program for the prevention of rheumatic fever: in Cuba, Costa Rica, and the French islands of Martinique and Guadeloupe (curve C, Fig. 83-1).^{4,16}

Finally, the cost-effectiveness of primary prevention as a public health strategy for the prevention of rheumatic fever has been questioned.^{4,8} A study conducted in South Africa showed that a strategy of using a clinical decision rule to diagnose GAS pharyngitis without culture and to treat it with a single intramuscular injection of penicillin is a cost-effective strategy for the primary prevention of rheumatic fever in a high-risk community.³³ A strategy of culture for all children is prohibitively expensive. Taken together with the clinical trial evidence,¹¹ the findings suggest that primary prevention by treatment of symptomatic cases of GAS pharyngitis diagnosed on clinical grounds may be a cost-effective public health strategy for the prevention of rheumatic fever in the context of a comprehensive national program for prevention of the disease.²⁷

Secondary Prevention

A systematic review of the effectiveness of antibiotics in the secondary prevention of rheumatic fever reported two principal findings.²⁹ First, evidence from clinical trials is strongly in support of the superiority of

TABLE 83-5 Drug Regimen of Choice for the Secondary Prevention of Rheumatic Fever

ANTIBIOTIC	MODE OF ADMINISTRATION	DOSE
Benzathine benzylpenicillin	Single intramuscular injection every 3-4 weeks	For adults and children ≥ 30 kg in weight: 1,200,000 units For children < 30 kg in weight: 600,000 units
Penicillin V	Oral	250 mg twice daily
Sulfonamide (e.g., sulfadiazine, sulfadoxine, sulfisoxazole)	Oral	For adults and children ≥ 30 kg in weight: 1 g daily For children < 30 kg in weight: 500 mg daily
Erythromycin	Oral	250 mg twice daily

From WHO Technical Report Series No. 923. Rheumatic Fever and Rheumatic Heart Disease: Report of a WHO Expert Panel, Geneva 29 October-1 November 2001. Geneva, WHO, 2004.

TABLE 83-6 Duration of Secondary Prophylaxis for Rheumatic Fever

CATEGORY OF PATIENT	DURATION OF PROPHYLAXIS
Patient without proven carditis	For 5 years after the last attack or until 18 years of age (whichever is longer)
Patient with carditis (mild mitral regurgitation or healed carditis)	For 10 years after the last attack or at least until 25 years of age (whichever is longer)
More severe valvular disease	Life-long
After valve surgery	Life-long

From WHO Technical Report Series No. 923. Rheumatic Fever and Rheumatic Heart Disease: Report of a WHO Expert Panel, Geneva 29 October-1 November 2001. Geneva, WHO, 2004.

intramuscular over oral penicillin in preventing recurrences of rheumatic fever. Second, more frequent injections are more effective than injections every 4 weeks in preventing recurrence of rheumatic fever. The evidence is strong for injections every 2 weeks, with an almost 50% reduction in the risk for recurrence of rheumatic fever when compared with injections every 4 weeks. The evidence for injections every 3 weeks is less strong and may be even weaker if we take into account the systematic error introduced by inadequate randomization and allocation concealment in the studies. Despite this evidence, the WHO recommends intervals of 3 to 4 weeks for the secondary prevention of rheumatic fever (Table 83-5).²⁷

Recommendations regarding the duration of secondary prophylaxis are largely empiric and based on observational studies. The duration of prophylaxis should be individualized and take into account the socioeconomic conditions and risk for GAS exposure in that patient. Individuals who have suffered carditis, with or without valvular involvement, are at higher risk for recurrent attacks and should receive prophylaxis well into adulthood and perhaps for life. If the valvular heart disease persists, prophylaxis should be life-long. Patients who have not suffered rheumatic carditis may receive prophylaxis until 21 years of age or 5 years after the last attack (Table 83-6).²⁷

FUTURE PERSPECTIVES

The key challenge in controlling rheumatic fever is related to identification and removal of barriers to the translation of existing knowledge into policy, programs, and practice. There is good evidence that a comprehensive national program that includes primary and secondary preventive interventions is effective in reducing the incidence of rheumatic fever and rheumatic heart disease in endemic countries.⁴ There is consequently a need for cardiovascular physicians and other partners in endemic countries to work with their ministries of health to establish the national public health programs of prevention that were recommended by the WHO in 2001.²⁷

Efforts to prevent and control rheumatic fever will be assisted by improvement in access to and the development of better formulations of penicillin, identification of the 3% to 5% of individuals with a genetic susceptibility to rheumatic fever, and the development of an effective vaccine for GAS infection. Benzathine penicillin has been designated an essential drug by the WHO, but it is not available to all who need it in affected countries. Furthermore, the current formulations of injectable penicillin require frequent administration and follow-up, which imposes a heavy burden on the fragile primary health care systems in developing countries. There is thus a need not

only to improve access to high-quality benzathine penicillin but also to develop new long-acting formulations that will improve adherence and the effectiveness of prevention programs.

An understanding of the molecular genetic mechanisms underlying host susceptibility can provide important insight into its pathogenesis, which in turn can facilitate diagnosis, new treatments, and vaccine development. Currently, the syndromic Jones criteria are not very sensitive or specific in countries with a high incidence, and a test for susceptibility may increase specificity. Identification of all of the genetic susceptibility factors for rheumatic fever through whole-genome analysis may in the future lead to the development of a useful predictive genetic risk score for the disease and improvement in the Jones criteria.¹⁴

A safe, effective, and affordable vaccine designed to prevent GAS infections could have a major impact on the health of millions of people at risk for the development of rheumatic fever. Research over a period of several decades has yielded a number of different candidate vaccines in various stages of preclinical and clinical development. Vaccine development efforts have been hampered by several obstacles, which can be overcome by global collaborative efforts to identify key activities and secure financial resources that will accelerate the process leading to successful introduction of a safe and effective vaccine for the entire world.³⁴

BACKGROUND

Inflammatory rheumatic diseases have a long recognized relationship with the cardiovascular system. Because the treatment of many rheumatic diseases has improved considerably over the last 15 years and increased survival, the importance and complexity of this interrelationship have achieved prominence. Patients with multisystem rheumatic diseases may on occasion initially be evaluated by a cardiovascular specialist, a cardiologist, or a vascular or cardiothoracic surgeon, and early recognition of the immune-mediated basis of the cardiovascular disease reduces morbidity and mortality. The vasculature may represent a primary target organ of the underlying rheumatic disease and can be affected at numerous sites and at all levels. Thus large-vessel vasculitides may affect the entire aortic wall. Systemic sclerosis (SSc) commonly results in pulmonary arterial vasculopathy and pulmonary artery hypertension (PAH). Antineutrophil cytoplasmic antibody (ANCA)-associated systemic vasculitides (AASVs) affect arterioles preferentially. Antiphospholipid syndrome (APS) causes both venous and arterial thromboses. Cardiac complications of systemic lupus erythematosus (SLE) include coronary arteritis, pericarditis, myocarditis, and valvular heart disease. Renal artery stenosis leading to uncontrolled hypertension is a feature of Takayasu arteritis (TA), and occlusive lesions in the subclavian, axillary, or iliac arteries may lead to limb claudication in patients with TA and giant cell arteritis (GCA). Rheumatic diseases have equally important secondary effects on the cardiovascular system. Chronic systemic inflammation predisposes to endothelial dysfunction and increased arterial stiffness, thereby escalating risk for the development of atherosclerosis. Cardiovascular specialists are increasingly recognizing the significantly increased prevalence of premature myocardial infarction and stroke in patients suffering from rheumatoid arthritis (RA) and SLE. Many outstanding clinical challenges remain, and predominant among them are early recognition and diagnosis of patients with rheumatic disease who have the highest risk for cardiovascular complications, alongside improved understanding of

the underlying molecular mechanisms and the development of preventive strategies.

Accelerated Atherosclerosis in Rheumatic Diseases

Recognition of the role of inflammation in atherosclerosis has highlighted and stimulated study of the potential relationship between systemic inflammatory diseases and accelerated atherogenesis. This effort has substantially advanced our understanding of both the underlying pathogenic mechanisms and epidemiology. Current priorities include identification of patients most at risk and the development of preventive therapeutic strategies.¹ Evidence supporting an association between inflammatory diseases and accelerated atherogenesis is best developed for RA and SLE. In addition, ankylosing spondylitis, psoriatic arthritis, AASV, TA, and APS may all be associated with premature atherosclerosis. Cardiovascular specialists should consider an underlying inflammatory disease in young patients with otherwise unexplained angina, myocardial infarction, or stroke. Patients with a rheumatic disease who suffer a myocardial infarction have worse outcomes in terms of both heart failure and mortality than does the age-matched general population.²

Endothelial Dysfunction and Vascular Injury

Homeostatic mechanisms promote a quiescent, antithrombotic, anti-adhesive vascular endothelium and control vasodilation and permeability (see Chapters 41 and 49). Prolonged systemic inflammation such as that seen in RA and SLE may promote endothelial injury, increased endothelial apoptosis, and endothelial vasodilator dysfunction.

Traditional risk factors alone do not explain the increased burden of atherosclerosis, but inflammation may exacerbate the effects of classic risk factors.³ When compared with the general population, patients with systemic inflammatory diseases more commonly exhibit endothelial dysfunction and increased aortic stiffness.

Although the results of individual studies vary, effective treatment of the underlying inflammation may not always reverse the endothelial dysfunction or improve the aortic stiffness.^{4,5} This observation has led to the hypothesis that the systemic inflammatory environment may predispose to increased plaque instability and rupture, a conjecture supported by an autopsy study.⁶ Given the increased plaque burden reported, both accelerated atherogenesis and higher-risk plaque may contribute to the observed increased incidence of premature cardiovascular events.

Various molecular mechanisms mediate the increased risk for atherosclerotic disease and cardiovascular events. In addition to the traditional cardiovascular risk factors, disease-related factors may include effects of the proinflammatory cytokines tumor necrosis factor- α (TNF- α), interleukin-1 (IL-1), and IL-6 on endothelial activation, leukocyte adhesion, endothelial injury, and permeability. Increased endothelial cell apoptosis and diminished capacity for repair may contribute. Autoantibodies (e.g., antiphospholipid antibodies), CD4⁺CD28⁻ cytotoxic T cells, Th17/T_{REG} imbalance, complement deficiency or excessive activation, genetic polymorphisms, and the deleterious effects of drugs, including corticosteroids and cyclosporine, may also contribute.^{2,7}

Rheumatoid Arthritis

RA, an autoimmune, symmetric inflammatory polyarthritis with a female-to-male ratio of 3:1, affects up to 1% of the population in the Western world, with the onset of symptoms most commonly occurring between 30 and 50 years of age. Up to 80% of patients have a positive serum rheumatoid factor and/or anti-cyclic citrullinated peptide (CCP) antibody test. A systemic inflammatory response is evident, with low-grade fever, weight loss, raised erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), hypoalbuminemia, normochromic normocytic anemia, and thrombocytosis.

Atherosclerotic Disease in Rheumatoid Arthritis

A variety of studies have shown subclinical arterial disease with increased carotid intimal-medial thickness (IMT) and early plaque development. Although RA independently raises the risk for atherosclerosis, the precise mechanistic relationship between RA and atherogenesis remains unknown. Similarly, the mechanisms and long-term outcomes of abnormalities in myocardial perfusion and coronary flow reserve that have been reported in patients with RA and normal epicardial arteries remain to be established.⁸ A recent study of microvascular and macrovascular function in RA has suggested that the classic cardiovascular risk factors may influence endothelial function more than disease-related inflammation does.⁹ The initial abnormalities in vascular function may occur at or before the onset of RA symptoms. The direct effect of chronic inflammation on vascular endothelium may itself promote atherogenesis, in addition to exacerbating the actions of traditional cardiovascular risk factors. Moreover, the systemic inflammatory environment can contribute to the features of plaque and blood that promote cardiovascular events in patients with RA.

Patients with RA have increased classic risk factors for atherosclerosis. Tobacco smoking is associated with both cardiovascular risk and the development of RA. Similarly, insulin resistance and the metabolic syndrome are more common in RA. Patients with RA may have a particular dyslipidemic pattern that includes high triglyceride levels and low levels of high-density lipoprotein (HDL) and low-density lipoprotein (LDL) cholesterol.⁷ The risk for myocardial infarction in patients with RA is similar to that in those with diabetes mellitus,¹⁰ and women with RA are twice as likely as age-matched controls in the general population to suffer myocardial infarction. Although death rates from both heart attack and stroke are comparable to that in the general population, events occur at an earlier age, with 50% of premature deaths in patients with RA being a direct consequence of cardiovascular disease. The excess mortality becomes apparent 7 to 10 years after diagnosis and has been associated with persistent disease activity and the presence of rheumatoid factor and anti-CCP antibodies. Current evidence suggests that patients with RA who suffer a myocardial infarction are less likely to

receive acute reperfusion therapy and secondary preventive measures and thus have worse outcomes.¹¹

Treatment

Drug therapy for RA has undergone a remarkable evolution over the past 15 years, with a current focus on biologic therapies and aggressive management of early disease. Clinical trials have demonstrated that this approach reduces symptoms and structural damage to joints. It remains uncertain, however, whether drugs that control synovitis also confer vascular protection.

Methotrexate is now the most widely used disease-modifying antirheumatic drug (DMARD), and since its introduction, mortality from myocardial infarction in patients with RA has improved. Similar observations have been made for sulfasalazine and hydroxychloroquine. Patients who do not respond adequately to DMARD therapy should switch to biologic therapies. Such agents now include those targeting TNF- α (infliximab, adalimumab, etanercept, certolizumab, and golimumab), the IL-6 receptor (tocilizumab), CTLA4Ig (abatacept), and the B cell-depleting monoclonal antibody rituximab. An aggressive disease-modifying approach also minimizes the use of nonsteroidal anti-inflammatory drugs (NSAIDs) and the requirement for corticosteroid therapy. Glucocorticoids may adversely affect traditional risk factors such as insulin resistance, hypertension, and lipid profiles and may hasten carotid plaque formation in RA. Because NSAIDs and cyclooxygenase-2 (COX-2)-selective NSAIDs (coxibs), although effective, may elevate blood pressure and increase the frequency of thrombotic cardiovascular events, caution is required regarding their use in patients with cardiovascular complications of inflammatory disease. However, evidence suggests that NSAID use in patients with RA does not confer an increased risk for cardiovascular events, thus indicating that their anti-inflammatory effects predominate.¹²

Demonstration of the potential cardiovascular benefits of the biologic therapies will require the results of long-term prospective studies (see later). TNF- α promotes vascular endothelial activation and dysfunction and may lead to plaque destabilization, and hence blockade would appear to be an attractive therapeutic option. Infliximab therapy may improve endothelial function as measured by flow-mediated dilation 4 to 12 weeks after infusion, whereas etanercept has been reported to reduce aortic stiffness. In contrast, a recent study found no change in macrovascular function in response to TNF- α blockade at 3 months,⁹ and infliximab therapy for 3 years had no effect on carotid IMT in patients with RA in comparison to controls. Data from the British Society of Rheumatology Biologics Register are more encouraging. Despite no reduction in the incidence of myocardial infarction in patients treated with a TNF- α antagonist as opposed to conventional DMARDs (methotrexate, sulfasalazine, and hydroxychloroquine), infarction was markedly reduced in anti-TNF- α responders versus nonresponders.¹³ Thus tight control of RA disease activity per se appears to have a beneficial effect on the risk for myocardial infarction. Treatment of the arthritis must be combined with a careful review of classic risk factors and appropriate steps taken to modify these factors. Although precise guidelines are awaited, most rheumatologists have a low threshold for addition of a statin, with the goal being a target LDL cholesterol level lower than 3.37 mmol/liter and HDL cholesterol higher than 1.04 mmol/liter.⁷

Systemic Lupus Erythematosus

SLE, a systemic autoimmune disease, predominates in women at a ratio of 9:1 and affects all racial groups but more commonly those of Afro-Caribbean, Asian, and Chinese extraction. The reported prevalence varies from 4 to 280 per 100,000 population. Constitutional symptoms at initial evaluation include night sweats, lethargy, malaise, and weight loss. Frequent mucocutaneous features include the classic butterfly facial rash, oral ulcers, and alopecia. Serositis, myalgia, arthralgia, and Jaccoud nonerosive arthropathy also occur. Potentially life-threatening complications include glomerulonephritis leading to renal failure, central nervous system (CNS) involvement with cerebral vasculitis, pneumonitis, shrinking lung syndrome, and

PAH. Hematologic involvement includes lymphopenia in most and frequently hemolytic anemia, neutropenia, and thrombocytopenia. Cardiac manifestations of SLE are relatively rare but include pericarditis, myocarditis, endocarditis, aortitis, and coronary arteritis. Understanding of the pathogenesis of SLE has improved significantly in recent years. A defect in the clearance of apoptotic cells results in the exposure of nuclear antigens to an immune system with hyper-reactive B cells. Loss of immune tolerance results in the generation of autoantibodies and immune complexes. Deposition of immune complexes in target organs leads to activation of complement and tissue injury.¹⁴

Most patients have high-titer antinuclear antibodies and antibodies against double-stranded DNA (dsDNA). The latter are more specific for the diagnosis of SLE, and this is reinforced by the presence of antibodies against one or more nuclear antigens, including Sm, Ro, La, and ribonucleoprotein (RNP). Complement activation and consumption of C3 and C4 leading to reduced plasma levels characterize active disease. The ESR also rises in active disease, but CRP levels typically remain normal except in those with serositis or secondary infection.

Atherosclerotic Disease in Systemic Lupus Erythematosus

A bimodal peak in SLE-related mortality was first reported in the 1970s. The early peak was associated predominantly with active SLE and infectious complications secondary to immunosuppressive therapy, whereas coronary artery disease caused most deaths in the second peak. Since then, a variety of studies have suggested an increased risk for myocardial infarction and stroke in patients with SLE that is between 2-fold and 10-fold and up to 50-fold greater than that in the general population. The young age of patients with SLE and cardiovascular disease (67% of female patients with SLE and a first cardiac event are typically initially seen before 55 years of age) suggests that SLE accelerates arterial disease. In an inception cohort of 1249 patients monitored for 8 years, 97 vascular events were recorded, 31 of which resulted from atherosclerotic disease.¹⁵ Although the pattern of coronary artery disease in SLE does not appear to differ (**Fig. 84-1**), the plaque may be more vulnerable to rupture. Patients with SLE have worse outcomes following myocardial infarction than the age-matched general population does, with a higher risk for the development of cardiac failure and increased mortality.² This difference may result from late diagnosis of ischemic heart disease and a reluctance to treat aggressively.

Hypertension is common in SLE because of the presence of renal disease and the use of glucocorticoids in many patients. Similarly, patients with SLE commonly have metabolic syndrome, which is associated with renal impairment, higher corticosteroid doses, and Korean or Hispanic ethnicity.¹⁶ Patients with SLE also have lipid

abnormalities, including high levels of very low-density lipoprotein (VLDL) and triglycerides, elevated or normal LDL cholesterol, and reduced HDL cholesterol. Moreover, proinflammatory HDL leading to increased oxidatively modified LDL cholesterol was seen in 45% of patients with SLE as compared with 20% of those with RA and 4% of the general population.^{2,7} Antibodies against oxidized LDL also occur in SLE and may promote atherogenesis.

Treatment

Mild SLE with rash and arthralgia can be treated with simple analgesics and NSAIDs, with the addition of hydroxychloroquine if required. Mild to moderate organ involvement, including mild renal impairment, hematologic abnormalities, myositis, arthritis, and cutaneous lesions, requires the addition of prednisone and typically an immunosuppressant such as azathioprine, mycophenolate mofetil (MMF), or methotrexate to aid in controlling the disease and allow steroid-sparing therapy. Cyclophosphamide and high-dose corticosteroids remain the first-line treatment of life-threatening complications, including myocarditis, cerebritis, severe hematologic involvement, and glomerulonephritis. MMF is increasingly being used in place of cyclophosphamide for lupus nephritis because of its equivalent efficacy and concerns regarding the risk for permanent infertility seen in up to 50% of patients treated with cyclophosphamide. Most rheumatologists consider rituximab an effective treatment of severe SLE, although clinical trials to date have proved disappointing, which may reflect the high doses of corticosteroids used in these trials and consequent masking of the benefits associated with rituximab. A variety of regimens have been used, including combinations of rituximab, prednisone, and cyclophosphamide. Belimumab, a monoclonal antibody that binds to the soluble B lymphocyte stimulator and prevents its interaction with B cell surface receptors, has a modest disease-modifying effect in patients with moderate non-renal-related SLE.

Defining effective strategies for prevention of cardiovascular disease in patients with SLE will require long-term prospective trials with adjudicated cardiovascular endpoints. Undertreated and/or persistently active disease has been associated with accelerated atherogenesis. Therefore adequate individualized immunosuppressive therapy should minimize cardiovascular complications. Hydroxychloroquine reduces LDL cholesterol and lowers mortality from cardiovascular disease in patients with SLE. Aggressive management of traditional risk factors is also advocated, including diligent monitoring and tight blood pressure control. Statins are widely used, particularly in patients with renal impairment. Caution should be exercised in patients with active myositis, however, because statin therapy can exacerbate this complication. The clinical data available do not support significant protection against atherosclerosis by statins 2 to 3 years after initiation, although longer-term analysis is awaited.¹⁴

FIGURE 84-1 Atherosclerosis in SLE. **A**, Transaxial T2-weighted CMR of the carotid bifurcation showing atherosclerotic plaque (arrow). The lipid-filled core and fibrous cap can be seen along with evidence of calcification. **B**, CMR showing a two-chamber view in the late phase after gadolinium injection. Subendocardial late gadolinium enhancement is present in the anteroapical left ventricle (arrows) and extends from the base of the heart to the midventricular region, consistent with a previous subendocardial myocardial infarction.

Atherosclerosis in Association with Other Rheumatic Diseases

The relationship between chronic inflammation and atherogenesis implies that many rheumatic diseases may be associated with premature and increased cardiovascular risk (Table 84-1). Because data in support of this hypothesis are derived from relatively small studies, important current clinical challenges include the need to determine (1) which rheumatic diseases pose the greatest cardiovascular threat, (2) a means of identifying subsets of patients most at risk, and (3) preventative strategies to minimize cardiovascular events.

Ankylosing spondylitis, psoriatic arthritis, and gout may also be associated with atherosclerotic disease. Hyperuricemia independently predicts cardiovascular disease, and patients with gout often have hypertension, hyperlipidemia, obesity, and diabetes mellitus. Many drugs used for the treatment of cardiac disease, including diuretics, beta blockers, and low-dose aspirin, can increase serum uric acid levels. In contrast, losartan, angiotensin-converting enzyme (ACE) inhibitors, atorvastatin, and fenofibrate may reduce urate levels.¹⁷ Allopurinol may reduce the risk for congestive cardiac failure and cardiovascular-associated death. In addition to achieving a serum uric acid level lower than 0.36 mmol/liter, patients with gout should receive dietary advice and aggressive management of cardiovascular risk factors.

A systematic review of articles on cardiovascular disease in patients with psoriatic arthritis has revealed increased traditional risk factors, endothelial dysfunction, aortic stiffness, and subclinical atherosclerosis. The limited data available also suggest that adequate suppression of inflammatory disease activity leads to improvement in endothelial dysfunction and carotid IMT.¹⁸ Patients with ankylosing spondylitis have demonstrated impaired endothelial function and increased carotid IMT and pulse wave velocity, all of which indicate an increased risk for atherosclerosis.¹⁹ The impact of the increasing use of anti-TNF- α therapies on the incidence of cardiovascular events in these patients should emerge from international biologic registries.

VASCULITIS

The vasculitides, a heterogeneous group of diseases, represent a significant clinical challenge, both diagnostically and therapeutically. The primary systemic vasculitides are classified into large-, medium-, and small-vessel disease. This leaves a small group of unclassified conditions, including Behçet disease, relapsing polychondritis, primary CNS vasculitis, and Cogan syndrome.²⁰

The histologic features of vasculitis include perivascular inflammatory infiltrates that may invade the arterial wall, fibrinoid necrosis,

thrombosis, fibrosis, and scar formation. Fibrinoid necrosis, a specific feature of the medium- and small-vessel vasculitides, typically affects the inner layer of the tunica media. Complications include stenosis and occlusions resulting in organ ischemia, thrombosis, aneurysm formation, and hemorrhage. Although biopsy is optimal for making the diagnosis, suitable tissue may not always be accessible, or arterial biopsy may be considered too hazardous, such as in patients with TA. Thus diagnosis often depends on clinical findings, laboratory indices, and imaging.

The immunopathogenesis of the vasculitides is complex, multifactorial, and poorly understood. The endothelium may be subject to complement-mediated injury as a consequence of immune complex deposition in polyarteritis nodosa (PAN) or rheumatoid vasculitis. In the medium- and small-vessel vasculitides, ANCA may activate neutrophils and subsequently damage the endothelium. The proinflammatory cytokines TNF- α , IL-1, IL-6, and interferon-gamma (IFN- γ) may activate the endothelium and induce the expression of adhesion molecules, including E-selectin, vascular cell adhesion molecule-1 (VCAM-1), and intercellular adhesion molecule-1 (ICAM-1), thereby facilitating leukocyte adhesion and recruitment into the vessel wall and surrounding tissue.

Cardiovascular disease in patients with vasculitis, although relatively rare, can be life-threatening. Aortitis, hypertension, coronary arteritis, valvular heart disease, pericarditis, myocarditis, conduction abnormalities, accelerated atherosclerosis, and cardiac failure can all occur. This section focuses on the vasculitides most likely to be encountered by cardiovascular disease specialists.

Large-Vessel Vasculitis

Giant Cell Arteritis

GCA affects large and medium-sized arteries. The disease affects those older than 50 years, with incidence increasing with age. GCA occurs most commonly in northern Europe, Scandinavia, and the United States in people of northern European ancestry. GCA typically affects extracranial branches of the aorta and, in addition to the temporal arteries, may involve the subclavian and axillary arteries, the thoracic aorta, and on occasion the femoral and iliac arteries. Clinical features include fever, weight loss, malaise, headache, temporal artery thickening with loss of pulsation, scalp tenderness, and jaw claudication. The most feared complication, anterior ischemic optic neuropathy (AION), may be manifested as amaurosis fugax or sudden permanent visual loss. Up to 25% of patients are initially found to have systemic features without the classic sign of tenderness and temporal artery involvement. ¹⁸F-fluorodeoxyglucose positron emission tomography (FDG-PET) has confirmed earlier autopsy findings and shown widespread arteritis with increased FDG uptake throughout the aorta and subclavian and iliac arteries in more than 50% of patients.

Pathogenesis

Histopathologic examination reveals localized fragmentation of the internal elastic lamina closely associated with an inflammatory infiltrate consisting predominantly of IFN- γ -producing CD4⁺ T lymphocytes, monocytes/macrophages, and occasional characteristic multinucleated giant cells. Recent studies have revealed that activated CD83⁺ dendritic cells initiate the arterial wall inflammation and colocalize with activated T cells. Local synthesis of growth factors such as platelet-derived growth factor leads to concentric proliferation of smooth muscle cells and occlusion of the arterial lumen (Fig. 84-2). On occasion, release of matrix metalloproteinases and generation of reactive oxygen species result in arterial wall injury and aneurysm formation.

Diagnosis

Biopsy is the definitive means of diagnosis and should be considered for all patients. However, the need for biopsy should not delay treatment. Temporal artery biopsy is positive in up to 80% of patients. Recent interest has focused on temporal artery ultrasound, which can reveal a characteristic halo sign with concentric homogeneous

FIGURE 84-2 GCA. **A**, A temporal artery biopsy specimen stained with hematoxylin-eosin shows evidence of myofibroblast proliferation and vessel occlusion, a focal mononuclear cell inflammatory infiltrate, and the presence of multinucleated giant cells (arrow). **B**, Dark hypoechoic, circumferential wall thickening (halo sign) (arrows) is seen around the temporal artery lumen in active GCA in both the transverse and longitudinal views. **C**, ^{18}F FDG-PET-CT scan demonstrating uptake in the thoracic aorta and subclavian arteries (arrows), consistent with active arteritis. **D**, Magnetic resonance angiogram demonstrating stenosis of the left axillary artery (arrow) in a 70-year-old woman with upper limb ischemic symptoms. (**B**, Courtesy Dr. Wolfgang Schmidt, Medical Center for Rheumatology Berlin-Buch, Berlin, Germany.)

thickening of the arterial wall and evidence of flow disturbance and stenosis (Fig. 84-2).

Cardiovascular Complications

Although rare, severe cardiovascular complications can occur and include dissecting thoracic aortic aneurysms (Table 84-2). Imaging and autopsy studies suggest that aortitis and aortic wall thickening are frequent in GCA, although their relationship with the development of aortic aneurysm remains unclear. Increased FDG uptake in the thoracic aorta has been associated with an increased risk for aortic dilation.²¹ Overall, patients with GCA have a 17-fold increased risk for thoracic aortic aneurysms. The risk is higher in those with conventional cardiovascular risk factors, poorly controlled disease, and aortic regurgitation. In the absence of guidelines, we recommend annual thoracic aortic screening for those with FDG-PET-positive thoracic aortic uptake or magnetic resonance angiography (MRA) or computed tomography angiography (CTA) evidence of aortic wall thickening and every 2 to 3 years in the remainder of patients. CTA and MRA are the optimal imaging techniques. Pericarditis, coronary

arteritis, limb ischemia, accelerated atherosclerosis, myocardial infarction, and cerebrovascular accidents are all associated with GCA. Yet most outcome studies do not report increased mortality, so the impact of severe cardiovascular disease seems to be small.

Takayasu Arteritis

TA, a granulomatous panarteritis, affects the aorta and its major branches, typically before the age of 40 years. The disease predominates in women, with a female-to-male ratio of up to 10:1. Because the diagnosis is often delayed, substantial arterial injury accrues. The current diagnostic criteria depend on detection of established stenotic disease and do not yet reflect the increasing sensitivity of non-invasive imaging.²²

Initial symptoms typically include nonspecific complaints such as fever, night sweats, arthralgia, malaise, profound tiredness, and lethargy. TA may be accompanied by symptoms of Raynaud phenomenon or upper extremity claudication, and carotidynia occurs in up to 25% of patients. The aorta may be involved throughout its length, and even though any branches can be diseased, the most commonly

TABLE 84-2 Cardiovascular Disease in the Systemic Vasculitides

VASCULITIDES	CARDIOVASCULAR COMPLICATIONS
Large-Vessel Vasculitis	
Giant cell arteritis	Thoracic/abdominal artery aneurysm, limb ischemia, pericarditis, coronary arteritis, IHD, MI
Takayasu arteritis	Aortic regurgitation, limb ischemia, aortic stenosis, aortic aneurysm, stroke, hypertension, coronary arteritis and aneurysm, IHD, MI, myocarditis, cardiac failure
Kawasaki disease	Coronary artery aneurysm, MI, myocarditis, pericarditis, valvular dysfunction, cardiac failure
Medium-Vessel Vasculitis	
Churg-Strauss syndrome	Myocarditis, pericarditis, coronary arteritis, cardiomyopathy, cardiac fibrosis, valvular dysfunction, MI
Polyarteritis nodosa	Myocarditis, pericarditis, coronary arteritis, coronary aneurysm, hypertension, cardiac failure
Granulomatous polyangiitis	Myocarditis, pericarditis, coronary arteritis, valvular heart disease, cardiac failure
Microscopic polyangiitis	Pericarditis, coronary microaneurysm, MI

IHD = ischemic heart disease; MI = myocardial infarction.

affected are the subclavian and common carotid arteries. Stenotic/occlusive arterial lesions are found in more than 90% of patients, whereas aneurysms are reported in approximately 25%. The pulmonary arteries are involved in up to 50% of patients, and aortic valve regurgitation and coronary arteritis may occur.

The consequences of TA are often severe, with 74% reporting compromised daily activities and 23% unable to work. In our cohort, survival rates at 10 years are higher than 95%; similarly, in the United States, 94% to 96% survival rates are reported, whereas in Korea the survival rate was 87% at 10 years. In Japan, 15-year survival rates have improved to 96.5%. However, the survival rate was reduced to 67% in a subset of patients with serious complications and/or a progressive disease course.

Pathogenesis

Arteritic lesions demonstrate adventitial thickening and focal leukocytic infiltration of the media with intimal hyperplasia. The infiltrate is composed of activated dendritic cells, T and B lymphocytes, macrophages, and multinucleated giant cells (Fig. 84-3). Growth factor-driven myofibroblast proliferation leads to intimal hyperplasia and fibrosis and subsequent arterial stenosis or occlusion. Local matrix metalloproteinase synthesis may predispose to aneurysmal dilation.

Diagnosis

Diagnosis of TA depends principally on the physician including the disease in the differential diagnosis. The variable nature of the

FIGURE 84-3 TA. **A**, Hematoxylin-eosin staining of a common carotid artery biopsy specimen obtained at surgery shows a focal mixed mononuclear cell inflammatory infiltrate with a multinucleated giant cell. **B**, Color Doppler ultrasound study showing concentric homogeneous arterial wall thickening with increased IMT and markedly impaired arterial flow (arrow). **C**, ¹⁸FDG-PET-CT scan demonstrating uptake in the aortic arch (arrow), consistent with active arteritis. **D**, MRA demonstrating stenosis of the left subclavian artery with collateral formation (long arrow), proximal stenoses in the right subclavian and left common carotid arteries (stars), proximal stenosis in the right renal artery (short arrow), and an atrophic left kidney.

TABLE 84-3 “Red Flags” for Takayasu Arteritis

<i>In patients younger than 40 years the following may indicate of TA:</i>
Unexplained acute-phase response (raised ESR and/or CRP)
Carotidynia
Hypertension
Discrepant blood pressure between the arms (>10 mm Hg)
Absent/weak peripheral pulse or pulses
Limb claudication
Arterial bruit
Angina

features of TA and the lack of constitutional symptoms in 30% to 50% of patients initially present a challenge to prompt diagnosis. In addition to improved physician awareness, a list of “red flags” that raise the possibility of TA is helpful (Table 84-3).²³ One’s index of suspicion must be high in young patients with an unexplained acute-phase response or hypertension. Similarly, common initial signs, including diminished or absent pulsation or arterial bruits, can suggest the diagnosis.

Laboratory abnormalities during active disease include raised ESR and CRP (in 75% of patients), often accompanied by normochromic normocytic anemia, thrombocytosis, hypergammaglobulinemia, and hypoalbuminemia. No specific autoantibodies or other serologic abnormalities exist, however. Noninvasive imaging is now the optimal means of diagnosis because tissue biopsy is rarely available. High-resolution ultrasound, cardiac magnetic resonance (CMR), MRA, CTA, and PET have all been studied. Although the potential of these techniques is not in doubt, their specificity and sensitivity in the management of TA remain to be determined. ¹⁸F-FDG-PET-CT may reveal evidence of active arteritis and lead to early detection of prestenotic disease. A current consensus review has suggested that this technique is particularly useful for the detection of active arteritis in patients not receiving immunosuppressive therapy.²⁴ Demonstration of arterial wall enhancement, edema, or thickening on MRA and CTA may facilitate the diagnosis of prestenotic disease, and stenoses and aneurysms can be readily identified and monitored. Color duplex ultrasound is of particular use in assessing the common carotid and proximal subclavian arteries in TA. Homogeneous, bright concentric arterial wall thickening is a typical finding in affected common carotid arteries (Fig. 84-3).

Cardiovascular Complications

In addition to the sequelae associated with cerebral, internal organ, and limb ischemia, aneurysms, PAH, or aortic rupture may develop. Cardiac complications include aortic valve insufficiency, accelerated atherosclerosis, cardiac ischemia, myocardial infarction, and heart failure. Neither MRA nor ¹⁸F-FDG-PET-CT reliably identifies coronary arteritis. Coronary disease is often asymptomatic, as illustrated by the identification of silent myocardial injury in 27% of a cohort that we studied.²⁵ Patients with TA are also at risk from secondary accelerated atherosclerosis. Thallium stress scintigraphy revealed myocardial perfusion defects in 53%, whereas intra-arterial angiography has shown that up to 30% have coronary artery lesions typically affecting the ostia and proximal segments, with the left main coronary artery being most commonly affected.²⁶ Inflammation of the ascending aorta predisposes to coronary artery involvement, as well as to dilation of the aortic root with subsequent aortic valve regurgitation. In our cohort of 110 patients, 15% have required aortic valve replacement. Left ventricular dysfunction may affect up to 20% and is thought to reflect myocarditis, ischemic heart disease, and hypertension, a common finding often associated with renal artery stenosis in TA.

Kawasaki Disease

Kawasaki disease (KD) predominantly affects children younger than 5 years with a peak incidence at 6 to 24 months of age. The vasculitis affects medium and small arteries, notably the coronary arteries. All racial groups may be affected, and the highest incidence is recorded in Asia (20 to 100 per 100,000 children <5 years of age). KD is an acute

self-limited illness that typically resolves within 1 to 2 months, although mortality still remains 1% to 2%. Characteristic initial features include fever of 5 days’ duration or longer, bilateral conjunctivitis, and mucocutaneous lesions, including red fissured lips and a strawberry tongue. Cervical lymphadenopathy may be prominent, with erythema affecting the palms and soles and a polymorphous exanthema.

Pathogenesis

The cause of KD is unknown, although infection may trigger the disease and lead to an uncontrolled excessive immunologic response in a genetically susceptible host. The presence of occasional seasonal epidemics and increased incidence in siblings led to the infection hypothesis. A variety of organisms have been implicated, including streptococci, staphylococci, and *Propionibacterium acnes*. Despite this interest, no definitive evidence supports an infectious cause. Tissue specimens show endothelial injury, perhaps caused by proinflammatory cytokines and activated neutrophils. Infiltration of the arterial wall by neutrophils, T cells, and macrophages is associated with the development of arterial stenosis or, more commonly, aneurysms. Coronary artery aneurysms develop in up to 20% of patients during the first month of the illness, and 50% will regress in the following years.

Diagnosis

Neutrophilia, thrombocytosis, and a raised acute-phase response occur acutely. Echocardiography can detect coronary involvement from the second week of illness and can be used to monitor progress. Coronary angiography is not performed acutely because of the risk of precipitating myocardial infarction, but it can be used after 6 months to establish the degree of coronary artery injury. The electrocardiogram (ECG) demonstrates abnormalities in up to 50% of patients, including tachycardia, T wave inversion, ST depression, atrioventricular block, and rarely, ventricular arrhythmia.

Cardiovascular Complications

Coronary artery aneurysms develop in up to 25% of untreated patients with KD. Sudden death can occur as a consequence of myocardial infarction following acute coronary thrombosis or rupture of a coronary artery aneurysm. Pericarditis, pericardial effusion, myocarditis, valvular dysfunction, and cardiac failure may all occur, whereas peripheral arterial involvement is less common but may affect the limb, renal, and visceral arteries.

Treatment

Aspirin (80 to 100 mg/kg/day) in four divided doses is recommended, along with intravenous immunoglobulin (IVIG). This treatment combination has reduced the development of coronary artery aneurysm to 5%, with a significant impact on mortality. Twenty percent of cases are resistant to IVIG, however, and these patients can receive corticosteroids, although the results reported are variable.

The outcome for most patients with KD is good. Yet in up to 20% of those with coronary artery aneurysms, coronary stenoses eventually develop, and these patients require follow-up by an experienced cardiologist. Although the risk for long-term complications, including myocardial infarction and sudden death, is greater in those with giant aneurysms,²⁷ the risk for thrombosis and myocardial infarction still remains increased in those in whom aneurysms have regressed.

Idiopathic Aortitis

Aortitis can be a feature of SLE, Cogan syndrome, Behçet disease, human leukocyte antigen (HLA) B27–positive spondyloarthropathy, KD, and GCA. Aortitis may also be idiopathic in nature. The clinical features are nonspecific and include malaise, lethargy, chest pain, fever, and weight loss, and the diagnosis is often made only at the time of surgery. The ESR and CRP are typically raised, and the extent of the disease can be demonstrated by ¹⁸F-FDG-CT-PET scanning and aortic MRA or CTA (Fig. 84-4). Dilation of the aortic root may require aortic valve and root replacement, whenever possible preceded by immunosuppressive therapy to control aortic wall inflammation.

FIGURE 84-4 Idiopathic aortitis. **A**, ^{18}F -FDG-PET scan demonstrating high-grade tracer uptake (arrow) in the aorta from below the level of the arch to just above the level of the aortic bifurcation, in keeping with aortitis. The activity is largely concentric around the aortic lumen. **B**, MRA showing aortic ectasia.

Treatment involves corticosteroids and a steroid-sparing immunosuppressant drug such as azathioprine, methotrexate, or MMF.

Treatment of Large-Vessel Vasculitis

The evidence base for the treatment of large-vessel vasculitis is remarkably small. Although GCA and TA typically respond to steroids, the dose required to gain remission is high and the side effect burden is considerable. In GCA, the dependence on prednisone and conflicting evidence concerning the efficacy of steroid-sparing drugs, combined with concerns about AION, often result in overtreatment and significant side effects. Indeed, 86% of patients are found to have glucocorticoid-related adverse events at 10-year follow-up. In both these diseases the relapse rate is high when the dose of corticosteroid is tapered, thus suggesting that the vasculitis persists. Potential mechanistic insight into this comes from a recent report of two pathogenic pathways in GCA. Raised plasma IL-17 and infiltrating Th17 cells in the arterial wall were rapidly normalized by prednisone therapy and remained suppressed as the dose was reduced. In contrast, the Th1-promoting cytokine IL-12 and IFN- γ -producing Th1 cells demonstrated corticosteroid resistance, which may be responsible for the reemergence of disease.²⁸ Corticosteroid treatment of GCA should be tapered carefully to maintain remission and minimize side effects. Although the literature is somewhat conflicting, methotrexate and azathioprine represent suitable corticosteroid-sparing agents for those unable to sufficiently reduce the dose of prednisone, and currently, low-dose aspirin is recommended for all patients without a contraindication.²⁹ Steroid-sparing immunosuppressive drugs are required in most patients with active TA. Methotrexate and azathioprine are the most widely prescribed, and their use is supported by small open-label studies. In patients failing to respond or in those with life-threatening disease such as coronary arteritis, aggressive treatment with intravenous pulsed cyclophosphamide is recommended.²⁹

Anecdotal case reports suggest that anti-TNF- α therapy may be effective for the treatment of refractory GCA. However, a randomized placebo-controlled trial of the use of infliximab in 44 patients with GCA in remission with corticosteroids ended prematurely when it failed to demonstrate a benefit, either in terms of preventing relapse or as a steroid-sparing agent, and a second trial using etanercept only

showed a modest steroid-sparing effect.³⁰ Recent reports suggest that the anti-IL-6 receptor monoclonal antibody tocilizumab is effective in treating GCA.³¹ Open-label studies suggest that TNF- α blockade is an effective treatment in patients with TA who fail to respond adequately to combination therapy with prednisone and steroid-sparing immunosuppressant drugs, including cyclophosphamide. A recent review of all published cases of TA treated with TNF- α antagonists found complete remission in 37%, partial remission in 53.5%, and no response in 9.5%.³² Use of tocilizumab has been reported in a very small number of patients with TA. Patients have generally responded well, at least in the short term, and further data are awaited with interest.³¹ The suppression of both constitutional symptoms and CRP synthesis by tocilizumab complicates disease monitoring and may be falsely reassuring. It is therefore recommended that follow-up of patients with TA include angiographic monitoring, preferably with CMR because it avoids radiation exposure.

Critical analysis of the published results suggests that percutaneous angioplasty or bypass surgery requires caution in patients with TA or GCA. Indications for surgical intervention include aneurysmal enlargement with risk for rupture, severe aortic regurgitation or coarctation, stenotic or occlusive lesions resulting in severe symptomatic coronary artery or cerebrovascular disease, uncontrolled hypertension as a consequence of renal artery stenosis, and stenoses leading to critical limb ischemia. Whenever possible, surgery should be delayed until clinical remission is achieved with immunosuppression.³³

Medium-Vessel Vasculitis

The medium-vessel vasculitides include Churg-Strauss syndrome (CSS, allergic granulomatous polyangiitis), granulomatous polyangiitis (GPA; Wegener granulomatosis), and microscopic polyangiitis (MPA). Although these diseases have overlapping features, they represent distinct clinical entities. GPA is most frequently associated with a cytoplasmic ANCA (cANCA) staining pattern that recognizes the antigen proteinase-3, whereas MPA is most commonly associated with a perinuclear ANCA (pANCA) directed against myeloperoxidase.

Churg-Strauss Syndrome (Allergic Granulomatous Polyangiitis)

CSS is a systemic small-vessel necrotizing vasculitis with a prevalence of 10 to 14 per million population. Three disease phases are described. An initial prodrome characterized by allergic rhinitis, sinusitis, and asthma is followed by peripheral blood eosinophilia and eosinophilic infiltrative lesions in the lung and myocardium and usually, some years later, by a systemic phase with necrotizing vasculitis affecting the skin, peripheral nerves, gastrointestinal tract, and kidney (in 30%). Up to 40% of patients with CSS are ANCA positive and typically have pANCA. ANCA-negative patients are more likely to suffer cardiopulmonary complications, whereas pANCA-positive patients seem to be more at risk for renal and peripheral nerve involvement. The diagnosis depends on the clinical features, imaging studies, ANCA, and whenever possible, biopsy results. Patients have a markedly raised peripheral eosinophil count and evidence of necrotizing vasculitis, including eosinophilic infiltration (Fig. 84-5).

When contemplating a diagnosis of CSS, a number of alternatives need to be considered, including GPA and MPA. A history of asthma, the presence of significant peripheral eosinophilia, and a dense eosinophilic infiltrate are highly suggestive of CSS. Viral infections, including cytomegalovirus and hepatitis B and C, must be excluded. In light of the eosinophilia, parasitic infestation, particularly by helminths, should be sought and excluded. Eosinophilia in the absence of demonstrable vasculitis may represent idiopathic hypereosinophilic syndrome or an underlying leukoproliferative disorder.

Cardiovascular Complications

Of all the vasculitides, CSS is the most likely to be associated with severe cardiac disease (see Table 84-2). Cardiac involvement complicates up to 60% of cases, and the disease spectrum includes

FIGURE 84-5 CSS. **A**, Hematoxylin-eosin staining of a small artery (arrow) demonstrates fibrinoid necrosis and a dense perivascular mononuclear cell infiltrate. **B**, At higher magnification the inflammatory cells can be identified as predominantly eosinophils (long arrow) with scattered macrophages.

pericarditis, myocarditis, coronary arteritis, myocardial infarction, cardiac fibrosis, arterial thrombosis, and valvular dysfunction. Cardiac disease is a prominent cause of death. Cardiomyopathy occurs as a result of ischemia secondary to arteritis affecting the intramyocardial arteries or, less frequently, the epicardial coronary arteries. Myocarditis is associated with eosinophilic infiltration, fibrosis, and occasionally, granulomatous infiltration. Release of major basic protein and eosinophil-derived neurotoxin by infiltrating eosinophils can lead to direct tissue injury. Myocarditis can be life-threatening and may result in the development of restrictive, congestive, or dilated cardiomyopathy.³⁴

Investigation

Cardiac involvement in CSS requires urgent investigation and aggressive treatment (Fig. 84-5). Initially, a 12-lead ECG and transthoracic echocardiography are required. Common findings include evidence of left ventricular dilation in 30% of patients, reduced shortening fraction, and increased cardiac wall echogenicity. Wherever possible, contrast-enhanced CMR should be performed because it is the most sensitive means of detecting myocardial involvement.^{35,36} If the diagnosis remains in doubt, endomyocardial biopsy may reveal eosinophilic infiltration with or without fibrosis, although vasculitis is rarely seen and the patchy nature of the disease results in low diagnostic yield.

Treatment

The response to high-dose corticosteroids is typically good and associated with remission of disease in 90%. Relapses occur frequently on tapering steroid therapy, and prednisone-related side effects are common. In the presence of severe disease, including cardiac, gastrointestinal, CNS, and renal involvement, an immunosuppressant drug should be prescribed concomitantly. Although further clinical trials are required, the first choice of drug is pulsed intravenous cyclophosphamide. Once remission is achieved, generally by 3 to 6 months, cyclophosphamide can be replaced by azathioprine or methotrexate. In some patients with milder disease and evidence of steroid side effects, azathioprine or methotrexate should be added to aid in steroid tapering. In refractory disease, anecdotal case reports have suggested that IVIG or TNF- α blockade can be effective. B cell depletion has been used with variable success, and the results of ongoing clinical trials are awaited with interest.

Polyarteritis Nodosa

PAN is a rare disease characterized by a systemic necrotizing vasculitis of medium-sized arteries complicated by aneurysmal nodules. Viral infections, particularly with cytomegalovirus, human immunodeficiency virus, and hepatitis B and C virus, should be specifically sought and excluded. The classic type of PAN is an ANCA-negative vasculitis with the predominant clinical features including fever, malaise, arthralgia, weight loss, livedo reticularis, cutaneous nodules, and a vasculitic rash. Abdominal, cardiac, and testicular pain may

occur, and some patients manifest mononeuritis multiplex. Hematuria, proteinuria, and/or hypertension indicates renal involvement.

The pathogenesis of PAN remains poorly understood. The initial vascular endothelial injury is followed by local release of IL-1 and TNF- α , which predispose to chronic inflammation and upregulation of cellular adhesion molecules. Recruitment of neutrophils is followed by monocyte infiltration, local endothelial disruption, thrombosis, and fibrinoid necrosis (Fig. 84-6). The associated arterial wall injury predisposes to aneurysm formation. The diagnosis of PAN is not straightforward. Although a biopsy can be definitive, yield is variable and dependent on an accessible lesion. A deep skin biopsy specimen from an involved nodular site is optimal. Combined sural nerve and muscle biopsy may also be helpful. Occasionally, nodules are detected on a medium-sized peripheral artery that can safely undergo biopsy. Renal biopsy should be approached with caution because of the risk for hemorrhage from microaneurysms. Although noninvasive imaging with CTA or MRA is increasingly being used, mesenteric arteriography remains the most accurate way of identifying renal or hepatic microaneurysms.

Cardiovascular Complications

Cardiac involvement in PAN is often subclinical and clinically apparent in only 10% of patients. Congestive cardiac failure is most commonly seen and may be the consequence of a specific myocarditis or coronary arteritis. Alternatively, the underlying cause may be PAN-related renal disease complicated by hypertension. Pericarditis has been reported in 5% of patients, as well as supraventricular tachycardia and valvular disease. Coronary angiography may reveal coronary artery microaneurysms, coronary arteritis, or coronary spasm. Recently, coronary CTA has been investigated as an alternative and may demonstrate coronary artery aneurysms.

Treatment

Glucocorticoids form the basis of treatment of PAN. In those with cardiac disease, significant proteinuria with or without renal impairment, CNS involvement, gastrointestinal disease, or mononeuritis multiplex, intravenous cyclophosphamide therapy is used initially. Some physicians prefer oral cyclophosphamide, and although side effects are more common, time until relapse may be longer. Six months of cyclophosphamide is usually sufficient to achieve disease remission, and treatment can be switched to oral azathioprine. In those with refractory disease, infliximab given in combination with methotrexate or azathioprine may be of benefit.

Granulomatous Polyangiitis (Wegener Granulomatosis)

GPA is a granulomatous necrotizing vasculitis that commonly affects the sinuses, upper airways, lungs, skin, joints, and kidneys. Diagnosis is based on clinical features, biopsy evidence, and typically a positive cANCA with antibodies against proteinase-3. The disease may be confined to the upper airways or be more generalized and include ocular inflammation, cutaneous vasculitis, arthralgia, cavitating lung

FIGURE 84-6 PAN. **A**, Low-power photomicrograph of hematoxylin-eosin-stained sections of a nodular temporal artery biopsy specimen from a patient with PAN showing infiltration of the full thickness of the arterial wall by inflammatory cells. **B**, At higher magnification the inflammatory cells can be identified as predominantly lymphocytes, and there is evidence of fibrinoid necrosis. **C**, Right renal angiogram showing multiple small aneurysms (white arrow) and a normal calyceal system (black arrow). (From Mason JC, Cowie MR, Davies KA, et al: *Familial polyarteritis nodosa*. *Arthritis Rheum* 37:1249, 1994.)

FIGURE 84-7 GPA. Chest radiograph of a 36-year-old man showing pulmonary involvement with evidence of opacification and cavitation in the left upper lobe lesion (arrows).

lesions (Fig. 84-7), pulmonary hemorrhage, and acute renal failure. Clinical cardiac involvement is rare, although it has been reported in up to 30% of autopsy cases. The most frequently encountered problem is pericarditis, which can lead to hemodynamic compromise and tamponade. The presence of congestive cardiac failure is a poor prognostic sign and associated with 25% mortality in the first year. Underlying causes include coronary arteritis, myocarditis, and occasionally valvular heart disease.

Microscopic Polyangiitis

MPA is most commonly associated with glomerulonephritis, renal impairment, and pulmonary hemorrhage. Cardiac disease is rarely clinically significant, but pericarditis occurs in 10% of patients, and congestive cardiac failure develops in up to 18%. Subclinical and occasionally symptomatic acute myocardial infarction is seen. Evidence from case reports and small series shows that this disease also features symptomatic aortitis and coronary artery microaneurysms.

Investigation

Cardiac involvement should initially be investigated noninvasively with modalities that include rest or stress echocardiography. Contrast-enhanced CMR is a sensitive means of detecting myocardial pathology, and coronary CTA can demonstrate coronary arteritis and microaneurysms. Echocardiography suggests that valvular thickening is a common and typically asymptomatic finding in GPA. Aortic valve regurgitation may occur because of distortion and thickening of valve cusps or be due to aortic root dilation. On occasion, coronary artery catheterization may be required, and as for other vasculitides, it should be used cautiously in those suspected of having active coronary arteritis. When possible, steps should be taken to suppress disease activity with immunosuppressive therapy before angiography. Coronary arteritis is responsible for multiple small areas of myocardial infarction, which often remain clinically silent until the development of congestive cardiac failure. Occasionally, granulomas in conduction tissue can cause cardiac dysrhythmia.

Treatment

For both GPA and MPA, high-dose prednisone (1 mg/kg/day) is recommended and may be preceded by pulsed intravenous

methylprednisolone if indicated. Patients with the most severe disease, including pulmonary hemorrhage, severe cardiac disease, or significant renal impairment, receive pulsed intravenous cyclophosphamide to induce remission over the first 3 to 6 months. Cyclophosphamide can then be replaced with azathioprine, methotrexate, or MMF. In less severe limited disease, remission can be achieved reliably with prednisolone in combination with azathioprine or methotrexate.³⁷ Increasing evidence suggests that B cell depletion therapy is effective for AASV and achieves remission at a rate comparable to that of cyclophosphamide.^{38,39}

PERICARDITIS AND MYOCARDITIS

Pericarditis

Pericarditis commonly complicates the autoimmune connective tissue diseases, particularly SLE, SSc, and RA. Nonetheless, clinically significant pericarditis develops in fewer than 30% of patients. The reported prevalence ranges from 11% to 85%, depending on the type of study used to detect disease. Thus in necropsy studies, prevalence is high, with pericardial involvement reported in 40% of individuals with RA, 40% to 80% of those with SLE, and up to 70% of those with SSc. Pericarditis is diagnosed by echocardiography, which detects pericardial thickening or small effusions in up to 50% of these patients. CMR can also provide accurate definition of the extent of pericardial involvement.

Systemic Lupus Erythematosus

In SLE, pericarditis is usually associated with a flare of disease and often with polyserositis. The symptoms are typically mild and consist of chest pain, which is worse on lying flat, and dyspnea, which may have a pleuritic component. Complicated pericarditis is rare, and in only 1% to 2% is the effusion sufficiently large to cause cardiac tamponade. Constrictive pericarditis or infective pericarditis occur infrequently.

Rheumatoid Arthritis

Clinically significant pericarditis affects only 1% to 2% of patients with RA, more commonly male, seropositive patients. Constrictive pericarditis can develop over a period of months. Hemodynamically significant pericarditis, although reported, is extremely rare in patients being treated with antirheumatic therapy. Indeed, the more aggressive approach to management of RA and the increasing use of biologic therapies appear to have reduced the incidence of symptomatic pericarditis.

Systemic Sclerosis

Sclerodermatous disorders are rare, with the two most commonly encountered forms being diffuse cutaneous SSc (dSSc) and limited cutaneous SSc (lSSc). Following an initial vascular inflammatory phase, the predominant lesion is fibrosis, which affects multiple organs.⁴⁰ In addition to the severe cutaneous manifestations, common clinical features include arthralgia, telangiectasia, pulmonary fibrosis, PAH, and esophageal dysmotility. Renal crises are common and complicated by hypertension. Aggressive intervention is essential and includes the use of ACE inhibitors and calcium channel antagonists. This approach has transformed the prognosis. Pericardial disease is common and more frequent in those with dSSc and a history of renal crisis. Echocardiography typically demonstrates small pericardial effusions, which are rarely hemodynamically significant. Rapidly accumulating large effusions may occur occasionally.

Pericardial Fluid Analysis

Analysis of pericardial fluid is rarely useful diagnostically unless infective pericarditis is suspected. Immune complexes, antinuclear and anti-dsDNA antibodies, complement consumption, and normal glucose levels have been reported in pericardial exudates from patients with SLE. In RA the pericardial fluid glucose concentration

may be lower than that in plasma, and although rheumatoid factor activity is often detected, it is not considered diagnostic.

Treatment

In most cases a small pericardial effusion appears on a routine chest radiograph or echocardiogram and requires no specific treatment. In those with troublesome symptoms of pericarditis, a short course of a NSAID is used unless contraindicated. Low-dose oral prednisone may be required or used as an alternative. In addition and particularly in recurrent cases, further optimization of the regular immunosuppressive therapy is required. Pericardial fluid accumulation may be sufficient to cause hemodynamic compromise and even cardiac tamponade requiring pericardiocentesis or, in recurrent cases, a pericardial window. In immunosuppressed patients, pericardial fluid should be analyzed for an infective cause. Advice should be sought from a microbiologist to ensure that the correct specimens are sent, including those required to exclude tuberculosis.

Myocarditis

Myocarditis is a rare but recognized cause of mortality in patients with autoimmune rheumatic diseases and is most commonly seen in patients with SLE, SSc, and polymyositis or dermatomyositis. Importantly, although most commonly present in those with an established rheumatic disease, myocarditis may be an initial feature, and these conditions should be considered in the differential diagnosis of those with unexplained heart failure. The most common symptom of myocarditis is recent-onset exertional dyspnea with evidence of hypoxia.⁴¹ A patient with severe heart failure at initial evaluation is a rare finding, and echocardiography usually reveals relatively modest changes in ventricular size and function. PAH must be excluded. In addition to standard blood tests, the following should be requested: ESR, antinuclear antibody, antibodies against dsDNA and extractable nuclear antigens, rheumatoid factor, a myositis immunoblot screen, and complement factor C3 and C4 levels.

Systemic Lupus Erythematosus

Although the widespread use of more effective immunosuppressive regimens has reduced the prevalence of myocarditis in patients with SLE to fewer than 10%, much of which is subclinical, it remains an important and potentially life-threatening complication. Other potential causes of heart failure include hypertension, ischemic heart disease, valvular heart disease, and complications associated with renal failure.

The initial symptoms of myocarditis vary from low-grade fever, dyspnea, and palpitations to signs of severe heart failure. In addition to complement consumption, a raised ESR, and an increased titer of anti-dsDNA antibodies, the troponin I level may be markedly raised. Changes on the ECG are typically nonspecific and include sinus tachycardia, ST or T wave changes, and supraventricular or ventricular tachycardias. Echocardiography aids in assessment (Fig. 84-8). Functional abnormalities may include segmental, regional, or global wall motion abnormalities; chamber dilation; and a reduced ejection fraction. In contrast, left ventricular hypertrophy in SLE is more commonly associated with poorly controlled hypertension, whereas systolic and diastolic abnormalities in left ventricular function have been associated with both hypertension and ischemic heart disease. CMR can be used to detect myocarditis and myocardial fibrosis, and gadolinium or adenosine stress first-pass perfusion may demonstrate coronary microvascular dysfunction.²⁵ Indeed, two recent studies using CMR and PET identified coronary myocardial dysfunction and reduced coronary flow reserve in patients with SLE.^{8,42}

Opinion is divided on the use of endomyocardial biopsy. It will not permit a specific diagnosis of SLE per se. Biopsy may, however, demonstrate an underlying inflammatory cause and features suggestive of SLE. Histopathologic analysis typically reveals small focal areas of fibrinoid necrosis with infiltration of lymphocytes and plasma cells, along with evidence of the deposition of immune complexes closely associated with myocyte bundles. Immunofluorescent studies may reveal granular staining and deposition of complement in and around

FIGURE 84-8 Myocarditis in SLE. **A** and **C**, Four-chamber view, **B** and **D**, Left ventricular view. In a 20-year-old patient with dyspnea and active SLE, the initial echocardiogram (**A** and **C**) showed mild impairment of ventricular function. Following symptomatic deterioration, the echocardiogram was repeated 6 days later and demonstrated markedly increased thickening of the left ventricular wall with a bright signal suggestive of inflammatory infiltration. These findings were associated with substantial deterioration in left ventricular function.

myocardial blood vessels. Biopsy may also help exclude other potential causes of cardiomyopathy.

Systemic Sclerosis

Inflammatory myocarditis rarely results in symptomatic cardiomyopathy in patients with SSc; it affects mostly those with prominent skeletal muscle myositis. Echocardiography may demonstrate impaired diastolic and systolic function and a reduced ejection fraction, occasionally severe enough to cause cardiac failure. Endomyocardial biopsy most commonly reveals myocardial fibrosis. The fibrosis occurs focally and affects both ventricles. As with other lesions in SSc, microvascular disease is considered an important pathogenic factor. Reduced coronary flow reserve occurs commonly,⁴³ and subclinical myocardial ischemia probably contributes importantly to the ventricular dysfunction.

Myositis

Polymyositis and dermatomyositis affect the proximal skeletal muscles and can cause severe weakness. In dermatomyositis, additional characteristic cutaneous manifestations include a violaceous heliotrope rash, Gottron papules, and periungual erythema. In pediatric cases, subcutaneous calcification is common and vasculitis may lead to severe gut ischemia and hemorrhage. In adults, particularly those older than 60 years, dermatomyositis may be paraneoplastic in origin. In severe cases, myositis involves the myocardium and pharyngeal or respiratory muscles and can be life-threatening. Creatine kinase levels rise markedly, and electromyography demonstrates

fibrillation and polyphasic action potentials. Magnetic resonance imaging of the proximal limb muscles helps identify the muscles involved and most amenable to biopsy. Histopathologic findings include muscle fiber necrosis and regeneration, a predominantly CD8⁺ T lymphocyte infiltrate, and HLA class I expression. Clinically significant myocarditis affects only 3%. Echocardiography may reveal ventricular dysfunction, whereas endomyocardial biopsy specimens demonstrate interstitial and perivascular lymphocytic infiltrates, contraction band necrosis, variable cardiomyocyte size, and degeneration and patchy fibrosis. Overt cardiac failure is rare; more common are rhythm and conduction abnormalities, including left anterior hemiblock and right bundle branch block.

Other Causes of Myocarditis

Even though postmortem studies have revealed evidence of myocarditis in patients with RA, it is seldom manifested clinically or causes heart failure. Although heart failure affects patients with RA more than it does age- and sex-matched controls, it predominantly reflects atherosclerotic coronary artery disease.² Myocarditis is also rarely associated with other rheumatic diseases, including ankylosing spondylitis, adult Still disease, GCA, and TA.

Treatment

Cardiac failure following myocarditis associated with autoimmune disease is treated with standard protocols and supportive interventions (see Chapter 25). SLE-related myocarditis requires urgent corticosteroid treatment and, when severe, intravenous methylprednisolone, 1 g/day for 3 days, followed by oral prednisone, 1 mg/kg/day. These patients can also receive pulsed intravenous cyclophosphamide. For more modest disease, treatment can include the addition of or increased dosages of azathioprine or MMF. Some evidence suggests benefit of IVIG in resistant cases. Management of myocarditis complicating dermatomyositis or polymyositis uses a similar approach. Myocarditis in patients with SSc rarely requires aggressive treatment. Because high-dose corticosteroids increase the risk for renal crisis, early use of intravenous cyclophosphamide is favored.

VALVULAR HEART DISEASE (See also Chapter 63)

Clinically significant valvular disease can complicate many rheumatic diseases. Mechanisms may include direct damage to cardiac valve leaflets or aortic valve regurgitation as a consequence of aortitis affecting the ascending aorta.

Systemic Lupus Erythematosus

Valvular abnormalities occur commonly in patients with SLE, and necropsy studies have reported lesions in up to 75%. Verrucous endocarditis (Libman-Sacks endocarditis) and nonspecific valvular thickening are most commonly detected. Valvulitis with rapid valvular dysfunction has also been described but is rarely seen. Transthoracic echocardiography detects verrucae in 2.5% to 12% and thickening in 4% to 38%, which increases to 30% and 43%, respectively, in those undergoing transesophageal echocardiography. Libman-Sacks lesions typically affects both valve surfaces, most commonly the mitral valve. Active valve lesions contain immunoglobulins, fibrin

clumps, areas of focal necrosis, and a leukocytic infiltrate, whereas older healed lesions exhibit vascular fibrous tissue predisposing to scarring and valve leaflet deformity. These abnormalities may cause valvular regurgitation. Libman-Sacks endocarditis occurs more commonly in SLE complicated by antiphospholipid antibodies and can accompany primary APS.

Libman-Sacks endocarditis is generally asymptomatic and may not cause a murmur, perhaps because of the location of the lesions near the edge of the valves. Assessment of SLE patients with a murmur may not be straightforward, and bacterial endocarditis needs to be excluded. Echocardiography can help distinguish Libman-Sacks from infectious endocarditis, an important consideration in immunosuppressed patients. In contrast to the typically nonmobile vegetations of Libman-Sacks, bacterial vegetations are usually located at the valve leaflet closure line and demonstrate mobility that is independent of valve leaflet motion. The presence of Libman-Sacks lesions increases the risk for secondary infective endocarditis, and prophylactic antibiotic prophylaxis should be considered to cover high-risk procedures such as invasive dental treatment (see Chapter 64). Complications of SLE-related valvular disease are rare, with hemodynamic effects seen in fewer than 5%. Valve replacement may be required for symptomatic regurgitation and occasionally for stenosis. The verrucous lesions may also embolize or rupture and lead to a cerebrovascular accident or peripheral embolism. Chordae tendineae rupture may also occur.

Treatment

Most patients require no specific treatment, although annual echocardiography can be used to monitor valve function. The introduction of corticosteroid therapy may have reduced the prevalence of Libman-Sacks endocarditis, and thus prednisone treatment may be considered in those with early active lesions.

Seronegative Spondyloarthropathies

The seronegative spondyloarthropathies include ankylosing spondylitis, postinfectious reactive arthritis, inflammatory bowel disease-related arthritis, and psoriatic arthritis. HLA-B27 is associated with ankylosing spondylitis and reactive arthritis. The spondyloarthropathies share overlapping clinical features, including asymmetric, predominantly large-joint oligoarthritis, ocular inflammation, sacroiliitis, spinal disease, and enthesopathy. Ankylosing spondylitis and reactive arthritis commonly involve the aortic root and valve. Aortic valvulitis leads to aortic cusp thickening and retraction and subsequently to symptomatic aortic regurgitation, which may cause heart failure. Proximal aortitis affecting the ascending aorta leads to aortic root thickening and subsequently to dilation and aortic regurgitation, the prevalence of which is related to disease duration.

Treatment

Management of the spondyloarthropathies has traditionally consisted of NSAIDs and, in more severe cases, the addition of DMARDs such as methotrexate, sulfasalazine, and leflunomide. Although these agents have some efficacy in the treatment of peripheral inflammatory arthritis, they are largely ineffective for spinal inflammation. The use of TNF- α antagonists for ankylosing spondylitis and psoriatic arthropathy has markedly improved control of the disease, with beneficial effects on peripheral arthritis, spinal disease, and extra-articular complications, including uveitis.^{44,45} Although evidence is currently limited, initiation of biologic therapy in those with early signs and symptoms of aortitis may reduce the risk for cardiovascular complications, including aortic regurgitation.⁴⁶

Rheumatoid Arthritis

Valvular thickening is commonly associated with RA in echocardiographic studies and at autopsy but seldom causes clinical problems. Patients with seropositive RA and with prominent extra-articular nodular disease more frequently have valvular lesions. Echocardiography most commonly shows mitral valve involvement, with valve thickening, asymptomatic mitral regurgitation, and prolapse being

the predominant findings. Histopathologic examination of the valves demonstrates granulomatous nodular lesions. No specific treatment is indicated, although on occasion hemodynamically significant disease develops and requires mitral or aortic valve replacement.

Takayasu Arteritis

Cardiac valve dysfunction commonly complicates TA. In a recent series of 204 Korean patients, 23% had an abnormality in at least one valve, with regurgitation at the aortic valve found in 18% and at the mitral valve in 7.5%.⁴⁷ Inflammation of the ascending aorta predisposes to dilation of the aortic root with subsequent aortic valve regurgitation. Approximately 15% of patients require aortic valve replacement with or without aortic root replacement with a graft. If possible, surgery should follow control of disease activity with immunosuppressive therapy.

CARDIAC CONDUCTION DISTURBANCES

A variety of rheumatic diseases cause conduction abnormalities and cardiac rhythm disturbances. Usually, patients require no specific treatment beyond conventional management with antiarrhythmic drugs, ablation, or pacemaker insertion as required.

Systemic Lupus Erythematosus and Sjögren syndrome

Adult SLE seldom causes primary conduction abnormalities or rhythm disturbance, which may instead result from underlying ischemic heart disease or myocarditis. Female patients with SLE or Sjögren syndrome who test positive for antibodies against the Ro and/or La antigens carry the risk of bearing a child with congenital heart block, which may be complicated by myocarditis. These antibodies may cross the placenta and induce myocardial inflammation and can target the conduction system and lead to fibrosis. The precise incidence is not established, but the usual figures quoted are 1 case in 20,000 live births with a range of 11,000 to 25,000. Patients with SLE, the overlap syndromes, and Sjögren syndrome should be screened for anti-Ro and anti-La before pregnancy and be counseled appropriately. The fetus of mothers known to be antibody positive should be screened in utero by echocardiography every 2 weeks from 16 weeks of gestation onward. Incomplete atrioventricular block can reverse, and myocarditis may respond to dexamethasone therapy. Complete atrioventricular block is irreversible and associated with up to 20% mortality, with 65% requiring insertion of a pacemaker.

Systemic Sclerosis

Conduction system disease is common in SSc and affects up to 50% of patients. The patchy myocardial fibrosis characteristically associated with SSc may account for the abnormalities seen with disruption of the conduction pathways. Supraventricular arrhythmias are usually benign and amenable to treatment. Ventricular conduction abnormalities also frequently occur in SSc and may impair myocardial function. In these patients ventricular ectopy is common and closely associated with sudden death.

Spondyloarthropathies

Conduction abnormalities frequently complicate the HLA-B27-related spondyloarthropathies. In ankylosing spondylitis, up to 30% of patients experience conduction system disease, predominantly caused by subaortic fibrosis extending into the septum and affecting the atrioventricular node. Atrioventricular conduction block occurs commonly and may become complete.

Polymyositis and Dermatomyositis

Conduction abnormalities are the most common cardiac manifestation of the myositis syndromes. Left anterior hemiblock and right

bundle branch block occur most frequently and occasionally progress to complete heart block. The inflammation and fibrosis associated with polymyositis and dermatomyositis affect the conduction pathways, as demonstrated in 25% of autopsy cases.

Rheumatoid Arthritis

ECG screening studies in patients with RA have revealed arrhythmias or conducting system abnormalities in up to 50%, although they are usually clinically inapparent. Rheumatoid myocarditis and amyloid deposition in the heart can cause atrioventricular node conduction block. Similarly, rheumatoid nodules may disrupt the conduction system and cause all types of conduction abnormality.

PULMONARY ARTERIAL HYPERTENSION

PAH (see Chapter 74) can result from the connective tissue diseases and is of concern to rheumatologists as a significant cause of premature mortality (Table 84-4). PAH is often manifested late or goes undiagnosed. Furthermore, PAH frequently proves resistant to optimized treatment of the underlying connective tissue diseases. Notwithstanding, increased awareness, recognition of high-risk groups, improved screening, and novel therapies point toward a better outlook.

Systemic Sclerosis

SSc is the most resistant of the connective tissue diseases to treatment and has the highest mortality. PAH has very serious prognostic implications and is the most common single cause of SSc-related death.^{48,49} Novel therapeutic options offer renewed hope, and early data suggest improved survival.⁵⁰

Pathogenesis

Arterial remodeling is a central component in the pathogenesis of PAH and follows the differentiation of pericytes into vascular smooth muscle cells. Uncontrolled smooth muscle cell proliferation, deposition of extracellular matrix and subsequent fibrosis, vasoconstriction, and in situ thrombosis lead to increased pulmonary vascular

resistance. This is followed by right ventricular dilation, dysfunction, and failure. Because PAH may develop very rapidly, effective screening strategies for patients with SSc are essential to detect PAH and allow early therapeutic intervention.

Screening

The prevalence of PAH in patients with SSc is between 5% and 12%. Although more common with ISSc, PAH also frequently occurs in patients with dSSc. Debate continues regarding the frequency of screening and whether to include both symptomatic and asymptomatic patients. A recent study, however, suggested that screening of asymptomatic patients is associated with improved survival.⁵¹ PAH may occur as an early or late complication, and there is a lack of reliable predictive risk factors. Annual screening should include echocardiography and pulmonary function testing.⁴⁹ In the latter, the carbon monoxide diffusing capacity may predict the development of PAH and prognosis. Pulmonary fibrosis can also complicate SSc and may exacerbate PAH (Fig. 84-9). Echocardiographically assessed pulmonary artery pressure may miss early asymptomatic disease. Positive results from screening should be followed by diagnostic right-heart catheterization.⁵² The level of NT-pro-brain natriuretic protein (BNP) is related to the degree of right ventricular dysfunction and the severity of PAH.

Treatment and Outcome

The typical initial symptom of PAH is dyspnea, and the diagnosis is often delayed until clinical evidence of hemodynamic impairment is apparent, not the least because of the multiple potential causes of dyspnea in patients with SSc. Delayed diagnosis is also reflected in the very poor 3-year survival rate of 47% to 56%, thus emphasizing the need for early diagnosis and treatment, which may improve outcome.⁵² The aims of treatment have been summarized as improvement in New York Heart Association (NYHA) functional class and quality of life, delay in clinical deterioration, and improved long-term outcome. Although standard PAH outcome measures can be used to assess response to treatment (Chapter 74), not all of them have been validated in patients with SSc and they may be complicated by coexistent conditions, including pulmonary fibrosis and musculoskeletal pain. Treatment targets three main pathways. Endothelin-1 receptor antagonists include the dual receptor antagonist bosentan and the ET_A receptor inhibitors sitaxsentan and ambrisentan. Evidence from three clinical trials suggests that bosentan improves symptoms and/or survival in later-stage disease, and results from the EARLY trial have demonstrated improvement in NYHA class II disease. Sitaxsentan and ambrisentan may also have beneficial effects. The prostacyclin pathway may be targeted by epoprostenol, iloprost, or treprostinil, and open-label studies have shown improvements in symptoms and 6-minute walking distance. Similarly, the phosphodiesterase type 5 antagonist sildenafil improved exercise capacity in a placebo-controlled trial. Further studies should explore the effects of early targeted therapy and the use of agents in combination.⁴⁸

Systemic Lupus Erythematosus

The prevalence of PAH in patients with SLE varies between studies and was recently estimated to be between 0.5% and 17.5%.⁵³ Importantly, these patients are typically females of reproductive age, in whom PAH during pregnancy markedly increases the risk for mortality.

Pathogenesis

In situ pulmonary thrombosis or chronic thromboembolic disease leading to thrombotic arteriopathy is the most common cause of PAH in patients with SLE, and 83% of such patients have anticardiolipin antibodies. Additional causes include pulmonary arteritis, underlying interstitial lung disease, and left-sided heart disease secondary to myocarditis, hypertension, or ischemic heart disease.

Clinical Findings and Diagnosis

Dyspnea, which may be associated with fatigue, cough, and chest pain, is the typical initial symptom. The development of PAH does

TABLE 84-4 Pulmonary Arterial Hypertension in Rheumatic Diseases

RHEUMATIC DISEASE	FEATURES OF PULMONARY ARTERIAL HYPERTENSION
Systemic sclerosis	Prevalence of 5-12%. More common in ISSc
PM/Scl overlap	Annual screening recommended. Survival rate at 3 years of 47-56%
Systemic lupus erythematosus	Prevalence of 0.5-17.5%. Survival rate at 3 years of 74%. Thrombotic arteriopathy is the most common underlying cause. 83% of patients have anticardiolipin antibodies. Patients with severe Raynaud phenomenon, anticardiolipin antibodies, and anti-U1RNP require screening
Rheumatoid arthritis	Prevalence data limited; reported to be up to 20%. Clinically significant disease rare, often secondary to COPD, chronic thromboembolic disease, or interstitial lung disease. Improved RA treatment may result in a reduced incidence
Sjögren syndrome	PAH a very rare complication of Sjögren syndrome. Usually occurs late in the course of disease. Prevalence unknown
Takayasu arteritis	Pulmonary arteritis present in up to 50% of patients. PAH prevalence of 12%

COPD = chronic obstructive pulmonary disease; ISSc = limited cutaneous SSc; PM/Scl = polymyositis/scleroderma; RNP = ribonucleoprotein.

FIGURE 84-9 SSc. **A**, Chest radiograph of a patient with dSSc showing interstitial shadowing, mainly in the lung bases, along with associated loss of volume, consistent with early pulmonary fibrosis. **B**, CT of the thorax demonstrating ground-glass opacity, subpleural honeycombing with thickening of the interlobular septa, and linear fibrotic bands, in keeping with pulmonary fibrosis. There is also evidence of associated mild traction bronchiectasis. **C**, Pulmonary CTA in a patient with limited cutaneous scleroderma and pulmonary hypertension. The right atrium and right ventricle are enlarged, and there is dilation of the pulmonary trunk.

not necessarily reflect the duration of SLE or its severity. Although data concerning predictive features are limited, patients with severe Raynaud phenomenon, anticardiolipin antibodies, and anti-U1RNP antibodies are more susceptible. These patients should be screened annually with echocardiography to estimate pulmonary artery pressure. Raised pressure should be investigated further by right-heart catheterization.

Treatment and Outcome

Management of PAH in patients with SLE uses a dual approach that combines optimized immunosuppression and vasodilator therapy,⁵⁴ although protocols vary between centers.⁵⁰ Evidence on which to base therapeutic decisions in PAH associated with SLE is limited, and in many centers combination therapy is reserved for those with NYHA class III or IV disease. In contrast to SSc-related PAH, the response to increased corticosteroids and pulsed intravenous cyclophosphamide can be good, and once response is achieved, switching from cyclophosphamide to azathioprine or MMF can reduce toxicity. Stronger trial evidence is available for the use of vasodilator therapies, which include dual endothelin-1 receptor antagonists such as bosentan, prostacyclin therapy, and sildenafil. In those with anticardiolipin antibodies, life-long anticoagulation with warfarin is indicated. The 3-year survival rate of 74% is higher than that in patients with SSc-related PAH.⁵⁴

Rheumatoid Arthritis

Pulmonary complications in RA include pleural effusions, pulmonary nodules, interstitial lung disease, bronchiolitis obliterans, and occasionally PAH.⁵⁵ PAH in patients with RA most commonly results from other underlying diseases, including chronic obstructive pulmonary disease, chronic pulmonary thromboembolism, hyperviscosity syndromes, lung surgery, or left-sided heart disease. PAH may, however, be due to extra-articular manifestations of RA, pulmonary fibrosis, or isolated pulmonary arteritis. Dyspnea is the most common initial symptom. The diagnosis is often delayed, first because dyspnea is frequently attributed to other potential causes and, second, because of limited exercise capacity in patients with severe arthritis. Diagnosis of PAH by the measures outlined above should be followed by specific investigations such as high-resolution pulmonary CT, CTA, pulmonary function tests, and a ventilation-perfusion scan to determine the underlying cause. No specific guidelines are available for the treatment of PAH arising as a primary complication of RA. Any evidence of active RA should be treated aggressively and preferably with biologic agents such as TNF- α or IL-6 receptor antagonists. Specific treatment of PAH should also be considered, including the use of endothelin-1 antagonists or the phosphodiesterase type 5 inhibitor sildenafil.

Sjögren Syndrome

Clinically significant PAH is a very rare complication of Sjögren syndrome and usually occurs late, most typically in patients with NYHA functional class III or IV, and the diagnosis is established as described for RA above. Little evidence guides therapeutic decisions, and regimens vary considerably.⁵⁶ Therapy with corticosteroids and immunosuppressive drugs, including azathioprine and cyclophosphamide, should be optimized to gain control of the underlying Sjögren syndrome activity. This may provide at least transient benefit in PAH, particularly in patients with evidence of active interstitial lung disease. Anecdotal evidence suggests beneficial effects of B cell depletion therapy with rituximab in patients with severe disease and may offer a future approach for those with PAH. In patients failing to respond to enhanced immunosuppression or those with NYHA class III/IV disease, calcium antagonists, intravenous epoprostenol, bosentan, and sildenafil may stabilize and improve PAH.⁵⁶

Takayasu Arteritis

Pulmonary artery involvement in TA is often overlooked. Yet evidence of pulmonary arteritis is reported in 50% of patients with TA in

autopsy studies, and PAH develops in 12%. Even though pulmonary arteritis typically coexists with disease of the aorta, it can be isolated. Systemic hypertension and left ventricular dysfunction may cause secondary PAH. The pulmonary arterial lesions seen include stenoses, occlusions, and aneurysms. PAH may develop acutely early in the disease course or later following progressive pulmonary artery narrowing. When present, symptoms may include dyspnea, chest pain, and peripheral edema. These symptoms are often ascribed to other causes, including left ventricular dysfunction, and the diagnosis is typically delayed. Unless specifically sought, pulmonary artery involvement can be missed on initial radiologic studies. Dedicated CMR and contrast-enhanced CTA are the most sensitive modalities for detection. Abnormalities should be pursued with echocardiography and other studies as described above.

No clinical trials are available to guide therapeutic decisions. Aggressive treatment of the underlying arteritis with high-dose corticosteroids and a steroid-sparing drug such as methotrexate is recommended. Pulsed intravenous cyclophosphamide is typically reserved for nonresponders, and the emerging efficacy of biologic therapies for TA, including TNF- α and IL-6 receptor antagonists, suggests that they should be considered early in refractory disease. Warfarin is often used, particularly in those with evidence of thrombosis or pulmonary infarction. Bosentan or sildenafil may help in patients with more severe or resistance PAH.⁵⁷ Open reconstructive surgery or percutaneous angioplasty may prove successful.

THROMBOSIS IN THE RHEUMATIC DISEASES (See also Chapter 82)

Thrombosis is an important pathologic process in many rheumatic diseases and a cause of significant morbidity and mortality. Large-vessel thrombosis, both venous and arterial, can occur in Behçet disease and APS. Thrombosis in situ also occurs in small vessels, principally as the end result of chronic vessel wall hyperplasia or inflammation in diseases such as SSc, the vasculitides, and PAH. Chronic thromboembolic PAH can complicate SLE and SSc.

Activation of the coagulation cascade leading to thrombosis may be caused by abnormalities in the vessel wall, blood constituents, or blood flow (see Chapters 41 and 82). Abnormalities in endothelial function have particular relevance to rheumatic diseases. The prolonged systemic inflammation in patients with SLE, Behçet disease, and the vasculitides can cause endothelial apoptosis, a local inflammatory response, and endothelial activation. Cytokine-mediated endothelial activation disturbs anticoagulant mechanisms. Treatment of prothrombotic risk in these diseases requires consideration of approaches that include immunosuppression to control disease activity and minimize endothelial dysfunction, antiplatelet agents, anticoagulation, and the use of statins.

Antiphospholipid Syndrome (See also Chapter 82)

APS is associated with thrombosis (both arterial and venous) and with first-trimester fetal loss. Laboratory tests demonstrate antiphospholipid antibodies, most commonly anticardiolipin antibodies, and/or a positive lupus anticoagulant test. Anticardiolipin antibodies, typically of the IgG or IgM isotype and present in medium to high titer, or the lupus anticoagulant should be demonstrated on at least two occasions 6 or more weeks apart. Antiphospholipid antibodies directed against beta₂-glycoprotein-1 may activate the endothelium, monocytes, and platelets. This leads to surface expression of cellular adhesion molecules and generation of tissue factor by both monocytes and the vascular endothelium. The increased tissue factor and thromboxane A₂ synthesis by platelets results in a procoagulant state. Thrombosis requires a second hit, such as that provided by activation of the complement cascade. Antiphospholipid antibodies may also interact with other proteins in the coagulation cascade such as prothrombin, factor X, protein C, and plasmin and can adversely affect fibrinolysis. Recent laboratory studies have demonstrated that

FIGURE 84-10 Parasternal long-axis view of the heart from a patient with SLE and high-titer antiphospholipid antibodies. A massive vegetation is seen on the ventricular surface of the anterior mitral leaflet (arrows), but it is not interfering with valve mobility. LA = left atrium; LV = left ventricle; RVO = right ventricular outflow. (Courtesy Professor Petros Nihoyannopoulos, National Heart and Lung Institute, Imperial College London.)

antiphospholipid antibodies enhance leukocyte–endothelial cell interactions and induce thrombosis through inhibition of endothelial nitric oxide (eNOS) activation and nitric oxide biosynthesis. The mechanism involves binding of antibody to domain I of beta₂-glycoprotein-1 and impaired eNOS phosphorylation.⁵⁸

Cardiovascular Disease

Valvular abnormalities are the most frequently reported cardiac abnormality in patients with APS. The most commonly detected lesions are verrucous endocarditis (Libman-Sacks endocarditis) and nonspecific valvular thickening (see earlier) (Fig. 84-10). Although lesions are commonly found, clinically significant features are rare. Symptomatic disease is more frequent in those with high antibody titers. Congestive cardiac failure develops in up to 5% of patients, and 13% require cardiac valve replacement. Histologic analysis of the valves reveals deposition of antiphospholipid antibodies with complement activation. Occasionally, amaurosis fugax, transient ischemic attack, or stroke is seen as a consequence of arterial thromboembolism. Coronary thrombosis and myocardial infarction can complicate primary APS in 0.5% to 6% of patients, and intracardiac thrombi can also occur. APS in patients with SLE may enhance their risk for myocardial infarction and stroke.

Treatment

Confirmed thrombosis in patients with APS requires anticoagulation. Most centers target an international normalized ratio (INR) of 2.5 to 3.5. Some evidence supports the use of low-dose aspirin in patients with SLE complicated by antiphospholipid antibodies. In contrast, low-dose aspirin did not protect against deep venous thrombosis or pulmonary embolic disease in a study of men with primary APS.

Behçet Disease

Behçet disease occurs throughout the world but most commonly in Turkey, Iran, Japan, and Korea at 80 cases per 100,000 individuals, which falls to 4 to 8 per 100,000 in the United States, France, Germany, and the United Kingdom. This multisystem disorder includes orogenital ulceration, acneiform skin lesions, and arthralgia. It may be accompanied by uveitis and can cause blindness in the young. Arthralgia is common, and less frequently, patients suffer from meningoencephalitis, gastrointestinal ulceration, or vascular complications.

The vasculitis associated with Behçet disease predominantly affects the pulmonary arteries and veins, with thrombosis being a

prominent clinical feature. Most thrombi are venous and cause superficial thrombophlebitis and deep venous thrombosis, including superior vena cava obstruction, cerebral vein thrombosis, and Budd-Chiari syndrome. In a small number of cases, pulmonary arterial vasculitis leads to in situ pulmonary arterial thrombosis. Although small studies have suggested that thrombosis is linked to the concurrent presence of a prothrombotic condition such as factor V Leiden or prothrombin mutations, this is not thought to be the cause in most. Indirect evidence suggests that the procoagulant state arises from an activated, adhesive, and prothrombotic endothelium as a result of chronic vascular inflammation. A clinical trial comparing treatment of thrombosis in Behçet disease with anticoagulation, immunosuppression, or a combination of both therapies supports this hypothesis.⁵⁹ A higher proportion of patients treated with anticoagulation alone had recurrent thrombosis than did those prescribed immunosuppression. Pulmonary arterial aneurysms are a rare life-threatening complication in Behçet disease, and aneurysms may also be seen in other arterial beds. Other cardiovascular complications occur in less than 10% and include pericarditis, myocarditis, intracardiac thrombosis, myocardial infarction, and myocardial aneurysm.⁶⁰

Treatment

Scant clinical trial data are available to guide therapeutic decisions for the cardiovascular manifestations of Behçet disease. The European League Against Rheumatism (EULAR) guidelines recommend immunosuppression for the treatment of thrombosis,⁶¹ an approach common in endemic areas.⁶⁰ First-line treatment of these patients in emergency units in nonendemic areas is usually anticoagulation. This approach is appropriate because the cause of the thrombosis may not be immediately apparent, although patients with aneurysms have a substantial risk for bleeding. Patients should be seen in a specialist clinic for assessment of the need for long-term anticoagulation, immunosuppressive therapy, and noninvasive angiographic screening for aneurysms. Arterial aneurysms are treated aggressively with cyclophosphamide and high-dose prednisone to reduce inflammatory disease activity before surgical intervention, which may involve stenting via a percutaneous route or open surgical repair. Because the lesions often recur, patients require regular screening. Anecdotal evidence suggests that anti-TNF- α therapy is efficacious in those with recurrent aneurysms or those who fail to respond to cyclophosphamide.

ANTIRHEUMATIC DRUGS AND CARDIOVASCULAR DISEASE

Drug therapy for many rheumatic diseases has advanced dramatically over the past 15 to 20 years. Contributory factors include more accurate diagnostic tests, improved understanding of the mechanistic actions of drugs, and the development of novel targeted therapies. This section emphasizes the beneficial and deleterious effects of antirheumatic drugs on the cardiovascular system.

Relationship Between Drug Treatment and Cardiovascular Disease

Although inflammation contributes to atherogenesis and patients with systemic inflammatory rheumatic diseases have heightened risk for premature myocardial infarction and stroke, causality remains unproven.³ The impact of anti-inflammatory drugs on atherogenesis and the incidence of cardiovascular events might provide insight in this regard.⁴ To date, no clinical trial has convincingly demonstrated a beneficial effect of anti-inflammatory drugs on cardiovascular outcomes. Indeed, the traditional NSAIDs or coxibs actually lead to a small but measurable increased risk for thrombosis. NSAID use in patients with inflammatory arthritis does not appear to confer increased cardiovascular risk, thus suggesting that their anti-inflammatory role predominates.¹² Similarly, statins are known to reduce serum CRP levels, and large clinical trials suggest that in part, statins provide vascular protection independent of their

actions on LDL cholesterol, including immunomodulatory and anti-inflammatory effects.

Tumor Necrosis Factor-Alpha Antagonists

TNF- α blockade has proved to be an effective therapy for patients suffering from active RA. TNF- α can be targeted by monoclonal antibodies given intravenously or subcutaneously or by subcutaneous injection of etanercept, a soluble TNF receptor fusion protein. Their use is contraindicated in patients with established cardiovascular disease and evidence of NYHA class III and IV cardiac failure, and they should be used with caution in those with mild congestive cardiac failure.⁶² Although the results of separate studies are variable and the duration of benefit in some has been transient, TNF inhibition can improve endothelial function and aortic stiffness in patients with a variety of systemic inflammatory diseases.⁵ Evidence to date from the British Society for Rheumatology Biologics Register suggests that patients with RA who respond to anti-TNF- α therapy have a lower risk for future myocardial infarction than nonresponders do.¹³ A potential underlying mechanism for this effect has recently been reported.¹⁸ F-FDG-PET scanning revealed subclinical arteritis in patients with RA when compared with those with stable cardiovascular disease, and initiation of anti-TNF- α therapy suppressed the arteritis.⁶³ The next question is whether the extent of this subclinical arteritis can predict future cardiovascular events.

Interleukin-6 Inhibition

Tocilizumab, an inhibitor of IL-6 signaling, might be expected to have vasculoprotective effects and, at least in the short term, may improve both endothelial function and aortic stiffness. However, tocilizumab has an adverse effect on lipid profiles and may increase LDL cholesterol, thereby requiring the addition of a statin. Thus long-term prospective studies are now required to determine whether effective suppression of IL-6-driven chronic inflammation can reduce the risk for cardiovascular events, in addition to its established efficacy in the control of RA disease activity.

B Cell Depletion

Rituximab targets CD20 and depletes B lymphocytes. Initially established as a treatment of B cell lymphoma, rituximab can control RA disease activity and reduce erosions. Similarly, rituximab demonstrated efficacy equivalent to that of cyclophosphamide for the treatment of ANCA-associated vasculitis and may exert disease-modulating effects in SLE. Short-term studies (4 to 6 months) have suggested that rituximab improves lipid profiles, carotid IMT, and endothelial function.⁶² A recent study of 33 patients with active RA, however, found no change in arterial stiffness after 6 or 12 months therapy. Furthermore, rather than improving lipid profiles, LDL cholesterol was significantly increased.⁶⁴ Long-term, adequately powered clinical trials with primary cardiovascular endpoints are required. Severe cardiovascular complications have occurred following rituximab infusions. Regulatory agency advice is that this treatment should be used with caution and the infusion rate reduced in those with preexisting cardiorespiratory disease.

Methotrexate

Methotrexate in dosages up to 25 mg/wk has proved to be a remarkably effective treatment of RA and is widely used as a steroid-sparing drug in patients with the large-vessel vasculitides. Clinical evidence suggests that methotrexate has a cardiovascular protective effect, with those responding to methotrexate therapy demonstrating improvement in endothelial function. A recent meta-analysis confirmed early reports of a relative risk reduction in cardiovascular mortality of up to 70% in patients with RA prescribed methotrexate versus other DMARDs, although with a somewhat lower extent of protection.⁶⁵ The mechanisms underlying the vascular protection remain undefined.

Other Disease-Modifying Antirheumatic Drugs

The potential cardiovascular benefits of hydroxychloroquine, an antimalarial drug frequently used for the treatment of RA, SLE, and Sjögren syndrome, have become more widely recognized in recent years. Hydroxychloroquine has a cholesterol-lowering effect and may improve both endothelial function and aortic stiffness. Clinical studies have demonstrated that hydroxychloroquine reduces the risk for cardiovascular events in patients with both RA and SLE. In contrast, high cumulative doses have occasionally been associated with restrictive cardiomyopathy and with retinal damage.

Cyclosporine continues to be used for the treatment of rheumatic disease, including polymyositis, SLE, and RA, as well as in many patients following organ transplantation. Clinical studies suggest that cyclosporine impairs flow-mediated vasodilation. Laboratory investigations demonstrate that at least in part, this effect reflects reduced eNOS activity and nitric oxide bioavailability. The adverse cardiovascular effects seen with cyclosporine may also reflect its propensity to induce hypertension and renal impairment. Alternative immunosuppressive drugs, used predominantly in the transplantation scenario, include tacrolimus and rapamycin (sirolimus), which appear to have a more favorable vascular profile.

Glucocorticoids

Glucocorticoids have undisputed efficacy in the treatment of systemic inflammatory diseases, including RA, SLE, and the vasculitides. Yet the substantial side effect burden concerns patients and physicians alike. The influence of corticosteroid therapy on the progression of atherosclerosis is complex and dependent on the context. Their impact on blood pressure and glucose and lipid metabolism may have a deleterious effect. In contrast, in SLE, evidence suggests that insufficient use of glucocorticoids risks persistently active and/or relapsing disease, thereby leading to an increased risk for accelerated atherogenesis. Thus combination therapy with a steroid-sparing drug such as azathioprine, MMF, or methotrexate, which allows prednisone to be tapered to 7.5 mg/day or less, may be optimal, with no proatherogenic effect and potentially a vasculoprotective action. Indeed, this may also be the case in RA.⁶⁶

Statins (See also Chapters 42 and 45)

Large primary prevention trials indicate that statins can reduce cardiovascular morbidity and mortality, in part independently of changes in LDL cholesterol.⁶⁷ These actions have led to interest in statins as adjunctive therapy for rheumatic diseases, including RA and SLE, for which they have the potential to reduce disease activity and lower cardiovascular risk. The TARA trial demonstrated mild disease modulatory activity of statins in patients with RA.⁶⁸ Clinical trial evidence supporting the routine use of statins in all patients with RA and SLE is lacking. Although no guidelines exist, most rheumatologists currently consider the cardiovascular risk in patients with RA and SLE as being equivalent to that in patients with diabetes mellitus, and EULAR has suggested adding a 1.5× multiplier to standard cardiovascular risk calculations.⁶⁹ Indications for a statin include a LDL cholesterol level of 190 mg/dL or higher, a long history of RA, a family history of hyperlipidemia, higher age at disease onset, and the presence of any other cardiovascular risk factors.⁷⁰

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs and coxibs are important and effective drugs for the treatment of pain and inflammation. Concerns regarding atherothrombotic complications have, however, raised reservations regarding their use. As a consequence, patients with rheumatic disease are often denied these medications inappropriately. Although current evidence suggests that both classes have a small, manageable, and dose-dependent risk for cardiovascular complications, establishing the degree of risk and the relative safety profiles between individual drugs is difficult because of clinical trial heterogeneity and a lack of

TABLE 84-5 Cardiovascular Versus Gastrointestinal Risk in Prescribing Nonsteroidal Anti-Inflammatory Drugs

Patients with CV risk who are taking aspirin should avoid tNSAIDs or coxibs if possible
If essential, consider naproxen plus a PPI if GI risk is low or a coxib in those with significant GI risk
Cardiovascular risk varies between individual tNSAIDs and coxibs
Patients with cardiac failure or hypertension should avoid tNSAIDs and coxibs
Risk for a CV event with a tNSAID or coxib is <1% in those with <2 classic risk factors
Risk for a CV event may increase in older adults, men, and those with preexisting CV disease
Aspirin use increases the risk for GI events associated with tNSAIDs and coxibs
Coprescription of a PPI reduces the risk for GI events with tNSAIDs and coxibs
PPIs are more effective than H ₂ antagonists or misoprostol for gastroprotection
Gastrointestinal risk varies between individual tNSAIDs
Use the lowest effective dose for the shortest period

coxibs = COX-2-selective anti-inflammatory drugs; CV = cardiovascular; GI = gastrointestinal; PPI = proton pump inhibitor; tNSAIDs = traditional NSAIDs.

randomized controlled trial data for older NSAIDs. A recent network meta-analysis has suggested that no traditional NSAID or COX-2 inhibitor is entirely safe and that naproxen has the best cardiovascular profile as a result of its antiplatelet effects.⁷¹ Despite these reservations, the absolute risk for a cardiovascular event is very low, and gastrointestinal bleeding and perforation represent the major risk associated with NSAIDs (Table 84-5). Although coxibs are less likely to cause gastrointestinal problems, many guidelines recommend concomitant prescription of a proton pump inhibitor for patients taking either NSAIDs or coxibs for more than 10 to 14 days.

Concerns regarding a class effect of the coxibs arose from the APPROVE trial, which demonstrated increased thrombotic cardiovascular events with rofecoxib. The findings were reinforced by other clinical trials and by nonrandomized epidemiology studies in primary care. Many of these studies, however, compared coxibs with placebo and not with a NSAID. According to the hypothesis proposed to explain the findings, selective blockade of COX-2 leads to an imbalance between COX-1 and COX-2 enzymatic products such that the effects of thromboxane A₂ exceed those of prostacyclin, thereby predisposing to vasoconstriction, platelet aggregation, and thrombosis. This hypothesis depends on endothelial COX-2 being the predominant source of prostacyclin, and data are conflicted on this, with an important role for COX-1 emerging.⁷² Furthermore, data from studies comparing NSAIDs and coxibs in patients with arthritis, including the prospective TARGET and MEDAL trials, do not support a class effect based on COX-2 selectivity.⁷³ Additional findings from large population-based studies suggest that the NSAID diclofenac and the coxib rofecoxib have a particularly poor cardiovascular profile not shared by naproxen or celecoxib.⁷⁴ Finally, the study population is important, and few studies have looked in detail at patients with inflammatory arthritis. An inception cohort of 923 patients with early inflammatory arthritis was assessed for NSAID use and cardiovascular outcomes. The investigators demonstrated that exposure to NSAIDs was not associated with an increased risk for mortality and in fact led to a 2.5-fold reduction in cardiovascular mortality.¹²

Wherever possible, NSAIDs and coxibs should be avoided in patients with known ischemic heart disease, previous thrombosis, poorly controlled hypertension, and cardiac failure. In patients in whom anti-inflammatory drugs are being considered, an individualized assessment of both gastrointestinal and cardiovascular risk should be made. The patient should be encouraged to use these drugs when required and at the minimally effective dose rather than as a standing dose (Table 84-5).

FUTURE PERSPECTIVES

The current challenge is to design and perform adequately powered randomized clinical trials to investigate the efficacy of individual anti-inflammatory drugs in preventing atherosclerosis-related cardiovascular events. The data from available studies of antirheumatic therapies, although far from conclusive, do provide the impetus for further trials with large numbers of patients because of the relatively low incidence of cardiovascular events.³ The ultimate challenge is to test the hypothesis that a relatively aggressive anti-inflammatory approach, alongside conventional therapy, will confer additional benefit in those with known atherosclerotic coronary artery disease in the absence of an underlying rheumatic problem. Two such trials are planned: first, CIRT (Cardiovascular Inflammation Reduction Trial), in which methotrexate (10 to 15 mg/wk) will be compared with placebo, and second, the Canakinumab Anti-Inflammatory Thrombosis Outcomes Study (CANTOS trial), which will investigate the ability of an anti-IL-1 β approach to reduce the rate of recurrent myocardial infarction, stroke, or cardiovascular death.^{1,75}

Cardiac masses frequently present significant diagnostic and therapeutic clinical challenges. In many cases a cardiac mass is detected as an incidental finding and the resultant evaluation may culminate in confirmation of a cardiac tumor; however, this is generally an uncommon event because other cardiac masses, such as thrombus or vegetation, are generally much more common. This chapter begins by describing the initial symptoms and signs that may indicate a cardiac tumor, followed by an explanation of a typical evaluation process that depends heavily on current sophisticated imaging techniques. Once a cardiac tumor is suspected, the ultimate diagnosis is usually confirmed by biopsy or surgery because histologic diagnosis has a direct bearing on further treatment planning. The remainder of the chapter then focuses on delineation and potential management of cardiac tumors and the overall anticipated outcomes. It should be pointed out that this is an inexact science because of the relatively rare occurrence of cardiac tumors. Furthermore, the final pathologic diagnosis is typically confirmed after the bulk of decisions regarding treatment were made in advance of obtaining the final diagnosis.

CLINICAL MANIFESTATIONS OF CARDIAC TUMORS

Initial Decision Making

It is interesting to note that patients with cardiac tumors may initially have no symptoms or physical findings but exhibit abnormalities on imaging. Alternatively, there may be a host of nonspecific symptoms or findings on physical examination, and of course, there may be very specific and detailed symptoms or signs that should alert physicians to the possibility of a cardiac tumor (**Table 85-1**). The most important consideration in confirming the presence of a cardiac tumor is a high index of suspicion and integration of the symptoms, findings on physical examination, and imaging characteristics in a logical way to establish a clinically reasonable plan of action.

The initial evaluation is typically an imaging test such as two-dimensional echocardiography¹ or magnetic resonance imaging (MRI)^{2,3} in which a mass is identified. Depending on the characteristics of this mass and the known comorbid conditions of the patient, additional imaging may be undertaken, including three-dimensional echocardiography with contrast enhancement,⁴ MRI with gadolinium,^{5,6} coronary angiography to define the presence of coronary artery disease,⁷ position emission tomography (PET) to provide staging for cancer,⁷ or computed tomography (CT) to clarify intrathoracic structures.^{8,9} Transesophageal echocardiography (TEE) can also provide very specific anatomic information that is critical to planning treatment (**Table 85-2**).⁷

When assessing a cardiac mass as initial evaluation for a cardiac tumor, the clinical context in which the image was obtained is critical because the differential diagnosis of a cardiac mass is broad and includes tumors, thrombi, infection, and artifacts (**Table 85-3**). For example, if two-dimensional echocardiography shows an apical mass in a patient with new-onset heart failure, a cardiac tumor is less likely.¹⁰ The presence of a severe wall motion abnormality, as well as the fact that the mass may appear distinct from the myocardial wall and is lobulated, strongly suggests that the mass is much more likely to be a thrombus than a tumor (**Fig. 85-1**). Another scenario involves a patient with a history of melanoma that is metastatic to other organs and on routine cardiac imaging a solid mass is seen in an unusual location. Because there is no wall motion abnormality and no significant valvular disease or clinical signs suggestive of infective endocarditis, this mass is very likely to be a metastatic lesion to the heart (**Fig. 85-2**). A common consideration that may suggest a tumor, in regard to imaging, is movement of the mass and related structures during a motion image. If a tumor is infiltrating the myocardium, the involved myocardial area will not contract in normal fashion. A left ventricular myocardial apical mass contracting similar to that of surrounding tissue is likely to be either focal hypertrophy (**Fig. 85-3**) or left ventricular noncompaction^{11,12} (**Fig. 85-4**) as opposed to a cardiac tumor (**Fig. 85-5**). Furthermore, progression of an image over time may also indicate the pathologic process. If a cardiac mass changes in size from one image to the next, suspicion of a cardiac tumor is much higher. However, if an apical mass is stable for months or years, it is very unlikely to be a cardiac tumor. Of course, the exact nature and location of a mass are critical in determining whether it is likely to be a tumor.¹³ A classic example of this principle is lipomatous hypertrophy of the intra-atrial septum (**Fig. 85-6A, B**). The initial suspicion might be a myxoma or other tumor, but TEE revealing specific characteristics that are a hallmark of lipomatous hypertrophy will confirm the diagnosis.¹⁴

Classification of Cardiac Tumors

Cardiac tumors are divided into primary and secondary tumors. Primary cardiac tumors are very rare, with an autopsy incidence of 0.001% to 0.03%,¹⁵ and include benign or malignant neoplasms that may arise from any tissue of the heart. Secondary, or metastatic, cardiac tumors are 30 times more common than primary neoplasms, with an autopsy incidence of 1.7% to 14%.¹⁶ **Table 85-4** summarizes some of the pathologic descriptions of cardiac tumors that have been reported but is not an exhaustive list in that there have been many very specific pathologic descriptions reported and it can be difficult to adequately categorize them. Thus general categories will be discussed in the remainder of this chapter.

**TABLE 85-1** Range of Clinical Findings That May Indicate a Cardiac Tumor

Completely asymptomatic but an incidental abnormality on imaging
Low-grade fevers
Transient ischemic attack or cerebral vascular event
Positional dyspnea
Weight loss
Peripheral embolic events
Chest discomfort
Congestive heart failure
Upper extremity or neck swelling
Lower extremity venous thrombosis
Palpitations
Arrhythmias
Pericardial effusion/tamponade

TABLE 85-2 Common Testing That May Indicate the Possibility of a Cardiac Tumor

Two- or three-dimensional echocardiography
Chest radiography
Computed tomography
Magnetic resonance imaging
Transesophageal echocardiography
Position emission tomography
Nuclear scintigraphy

TABLE 85-3 Differential Diagnosis of Cardiac Masses

Intracardiac thrombus
Focal myocardial hypertrophy
Left ventricular noncompaction
Infectious (abscess)
Primary cardiac tumor
Secondary cardiac tumor (metastasis)
Lipomatous hypertrophy of the septum
Cyst
Imaging artifact

**FIGURE 85-1** A large irregular mass is present in the left ventricular apex (*arrow*) in the context of a patient with severe left ventricular dysfunction. The edges are distinct from the myocardium, a classic finding for a thrombus.**FIGURE 85-2** An irregular mass is noted on the atrial side of the tricuspid valve (*arrow*) in a patient with metastatic melanoma.**FIGURE 85-3** Four-chamber echocardiographic image showing focal apical hypertrophy (*arrow*) that resulted in severe diastolic heart failure. The apical mass contracted and was stable for years.**FIGURE 85-4** This apical mass is not solid (*arrow* in **A**), and color flow is detected in "lakes" within the apical mass (*arrow* in **B**). This is typical of noncompaction cardiomyopathy, and this area does appear to contract. LV = left ventricle.

FIGURE 85-5 An echodense area (arrow) did not contract and correlated with intense uptake on PET imaging in a patient with mediastinal T cell lymphoma. It resolved with treatment of the cancer.

BENIGN PRIMARY CARDIAC TUMORS

Most (>80%) primary cardiac tumors are benign, and myxoma is by far the most common.^{15,17} Myxoma constitutes about 50% of all benign cardiac tumors in adults, but only a small percentage of such tumors in children.¹⁸ Rhabdomyoma is the most common benign tumor in children and accounts for 40% to 60% of cases.¹⁷ Other benign cardiac tumors that have been described include fibromas, lipomas, hemangiomas, papillary fibroelastomas, cystic tumors of the atrioventricular node, and paragangliomas. The remaining 20% of primary cardiac tumors are malignant and usually described pathologically as sarcomas.¹⁹⁻²¹

Common Clinical Manifestations

Patients are commonly asymptomatic and the tumor is found as an incidental finding on two-dimensional echocardiography. When symptoms are present, dyspnea, especially dyspnea that is worse while lying on the left side, should alert an astute clinician to the possibility of a myxoma. Most signs and symptoms related to myxoma result from obstruction of the mitral valve (syncope, dyspnea, and pulmonary edema), followed by embolic manifestations.²⁰ Patients may also have nonspecific symptoms such as fatigue, cough, low-grade fever, arthralgia, myalgia, weight loss, and erythematous rash, as well as laboratory findings of anemia, increased erythrocyte sedimentation rate, and increased C-reactive protein and gamma globulin levels. Less commonly they may have thrombocytopenia, clubbing, cyanosis, or the Raynaud phenomenon. Findings on physical examination can reveal a systolic murmur or a diastolic murmur suggestive of mitral stenosis. A tumor plop may also be present (a low-pitched diastolic sound heard as the tumor prolapses into the left ventricle).²⁰ In one study a cardiac auscultation abnormality was detected in 64% of the patients²²; the most common abnormal auscultation findings are a systolic murmur (in 50% of cases), followed by a loud first heart sound, an opening snap, and a diastolic murmur. A systolic murmur may be caused by damage to the valves, failure of the leaflets to coapt, or narrowing of the outflow tract by the tumor. A diastolic murmur is due to obstruction of the mitral valve by the myxoma. Tumor plop may be confused with a mitral opening snap or a third heart sound and can be detected in up to 15% of cases.²² Chest examination may reveal fine crepitations consistent with pulmonary edema. Examination of the extremities may also reveal signs of an embolic phenomenon. The signs vary depending on the vascular territory involved. Involvement of the cerebral vessels results in neurologic signs, involvement of the coronary arteries may result in an acute coronary syndrome, intestinal arterial obstruction may result in an ischemic bowel, and peripheral arterial obstruction can result in limb-threatening ischemia.

Useful Investigations

Abnormal results on laboratory tests that can be useful may include anemia, elevated serum gamma globulin, elevated erythrocyte

sedimentation rate, and increased serum C-reactive protein. No electrocardiographic (ECG) findings are specific for myxoma. Chest radiographic findings are also nonspecific but include signs of congestive heart failure, cardiomegaly, and left atrial enlargement. In some cases the tumor itself may be visible because of calcification.²² Two-dimensional echocardiography should usually demonstrate a mass in the atrium with the stalk attached to the intra-atrial septum (see Fig. 85-8). TEE provides specific delineation of the tumor, including its size and origin. CT and MRI provide better delineation of the intracardiac mass, the extent of tumor in relation to extracardiac structures, and anatomic definition for preoperative planning.

Myxomas

Most myxomas (>80%) are found in the left atrium and in decreasing frequencies in the right atrium, right ventricle, and left ventricle. The incidence of cardiac myxoma peaks at 40 to 60 years of age, with a female-to-male ratio of approximately 3:1.²⁰ Most myxomas occur sporadically but may be familial, and occasionally they have been described in relation to a particular syndrome called the Carney complex, an autosomal dominant condition associated with cardiac myxomas, myxomas in other regions (cutaneous or mammary), hyperpigmented skin lesions, hyperactivity of the adrenal or testicular glands, and pituitary tumors. The Carney complex occurs at a younger age and should be considered when cardiac myxomas are discovered in atypical locations in the heart.¹⁹

Cause and Pathophysiology

The exact origin of myxoma cells remains uncertain, but they are thought to arise from remnants of subendocardial cells or from multipotential mesenchymal cells in the region of the fossa ovalis that can differentiate along a variety of cell lines. The hypothesis is that cardiac myxoma originates from a pluripotential stem cell and the myxoma cells express a variety of antigens and other endothelial markers. Myxomas typically form a pedunculated mass with a short broad base (85% of myxomas), but sessile forms can also occur.¹⁵ Classically, myxomas appear yellowish, white, or brownish and are frequently covered with thrombus (Fig. 85-7). Tumor size can range from 1 cm to larger than 10 cm, and the surface is smooth in most cases (Figs. 85-8 and 85-9). Myxomas may have a surface that consists of multiple fine or very fine villous, gelatinous, and fragile extensions that have a tendency to fragment.¹⁵ Histologically, myxomas are composed of spindle- and stellate-shaped cells with myxoid stroma that may also contain endothelial cells, smooth muscle cells, and other elements surrounded by an acid mucopolysaccharide substance. Calcifications may also be seen in some cases.¹⁵

FIGURE 85-6 Lipomatous hypertrophy. **A**, Classic TEE image of lipomatous septal hypertrophy. Note the dumbbell appearance and the thin area of the fossa ovalis (arrows). **B**, Four-chamber echocardiogram demonstrating lipomatous hypertrophy of the atrial septum in a 62-year-old man. The atrial septum superior to the fossa ovalis was found to have a thickness greater than 3 cm (arrow). **C**, Lipomatous hypertrophy of the atrial septum. **D**, Hematoxylin-eosin staining depicts variably hypertrophied and atrophied cardiac myocytes (arrows) with associated fibrous tissue and an admixture of mature (larger) and immature (smaller and granular) adipocytes (magnification: 200 \times). **E**, Movat pentachrome staining highlights the myocytes (purple) and associated excess collagen (tan), as well as the unusual adipose tissue (magnification: 200 \times). **E**, inset, Chloracetate esterase staining shows the presence of mast cells (magnification: 400 \times). Treatment

The only definitive treatment of cardiac myxoma is surgical removal. Generally, after median sternotomy the myxoma is excised surgically with the patient under cardiopulmonary bypass and cardioplegic arrest. The tumor is removed by either right or left atriotomy or combined atriotomy, depending on the site and extent of the tumor. The choice of technique also depends on associated conditions that need surgical intervention, such as valve repair or replacement and coronary disease if present. Life-long follow-up is needed because myxomas have some tendency to recur. Recurrence rates vary but range from 5% to 14%. The time to recurrence in different series has varied from 0.5 to 6.5 years.²²

Rhabdomyomas

Rhabdomyomas are usually located in the ventricle and are the most common benign cardiac tumor found in children.^{17,18} Most of these patients have signs or a family history of tuberous sclerosis.¹⁷ In one

study of patients with tuberous sclerosis complex, a cardiac tumor was found in 48%, with an incidence of 66% in patients younger than 2 years.²³ Frequently, these patients are asymptomatic, although some patients with rhabdomyoma may have clinical evidence of arrhythmias and heart failure.^{17,23} It is possible that these tumors may regress with age, but they can sometimes grow or develop during puberty.²³ As a result of these uncertain outcomes, long-term clinical and echocardiographic follow-up is needed in patients with tuberous sclerosis. Most often surgery can be avoided, although if the arrhythmias become symptomatic, antiarrhythmics and ultimately surgery may have to be considered.¹⁷

Fibromas

Histologically, fibromas are composed primarily of fibroblasts or collagen. They typically occur in childhood, although they can also develop in adults.^{15,20,24} Most often a fibroma is located in the ventricle and interventricular septum, and patients may have chest pain,

FIGURE 85-7 Atrial myxoma. **A**, Four-chamber echocardiogram of a left atrial myxoma in a 71-year-old woman showing a mass on the left side of the heart projecting from the atrial septum through the mitral valve into the left ventricle. **B**, Gross photograph of the left atrial myxoma that was surgically excised from the same woman. The tumor is a pedunculated, variegated mass with a friable, gelatinous texture. **C**, Hematoxylin-eosin staining of the loose, proteoglycan-rich tumor (magnification: 200x). The tumor is highly vascular, with vessels containing red blood cells admixed with lipidic cells present in a network throughout the tumor matrix (arrows). **D**, Movat pentachrome staining aids in defining the composition of a myxoma (magnification: 400x). A variably loose (bubbly *turquoise* appearance) glycosaminoglycan-rich connective tissue is interspersed with collagen (*yellow*), rare mononuclear cells, and lipidic mesenchymal cells (arrows, *magenta*). **E**, Immunohistochemical staining indicates prominent expression of versican (*golden brown*), a major proteoglycan in myxomas (magnification: 400x). **F-H**, Immunohistochemical staining for vessels was positive for alpha smooth muscle actin (arrow), CD34, and CD31, respectively (magnification: 400x). **I**, Staining for leukocyte common antigen is positive for mononuclear cells (magnification: 400x). **J**, Staining for CD68 shows several macrophages (arrows), some of which are laden with hemosiderin as a result of previous hemorrhage, a common occurrence in myxomas (magnification: 400x).

FIGURE 85-8 Large left atrial myxoma prolapsing across the mitral valve and resulting in heart failure symptoms. AMVL = anterior mitral valve leaflet; LV = left ventricle; RA = right atrium; RV = right ventricle.

pericardial effusion, heart failure, arrhythmias, and sudden death. Cardiomegaly is frequently seen on chest radiographs, which may also show calcification within the tumor mass.²⁴ Typically, these tumors are associated with arrhythmias and might require multimodality treatment consisting of medications, electrophysiologic procedures, and/or surgery. If surgical resection is performed, fibromas tend not to recur. A distinguishing feature of fibromas, in contrast to rhabdomyoma, is that calcification is frequently present.¹⁵

Lipomas

A lipoma is a rare benign cardiac tumor that represents just 3% of all benign tumors.²⁵ Lipomas tend to occur in the left ventricle or the right atrium but may be found anywhere in the heart, as well as in the pericardium (**Fig. 85-10**). Although frequently asymptomatic, they may grow large enough to cause obstructive symptoms.

Papillary Fibroelastomas

Valvular structures may have a papillary fibroelastoma, which is often found incidentally. They are small in size, typically less than 2 cm,

FIGURE 85-9 Gross appearance of a left atrial myxoma. Note the thrombus-appearing material on the surface (arrow), which is probably a mechanism for the embolic events associated with cardiac myxomas.

and most commonly occur on the aortic valve, followed by the mitral valve. Rarely, they may be found anywhere in the endocardial surface, and most fibroelastomas that have been reported are solitary, although multiple ones may be seen occasionally.²⁶ Fibroelastoma may result in embolic phenomena and, when situated on the aortic valve, can cause coronary ostial occlusion. Grossly, they have a characteristic frondlike appearance resembling a sea anemone, and histologically the tumor has an inner central core of collagen that is surrounded by a layer of acid mucopolysaccharides and covered by endothelial cells.²⁶ For the most part, complete surgical resection is recommended, mainly because of the high likelihood of systemic embolism (i.e., stroke, myocardial infarction, peripheral embolism, and even sudden death). On imaging, especially echocardiographic imaging, a papillary fibroelastoma has a characteristic small, mobile, pedunculated and very echodense core that enables it to be differentiated from a vegetation or thrombi. Once the tumor is removed completely, the chance of recurrence appears to be low, and there are no compelling data to continue anticoagulation in the long term unless other indications to do so are present.²⁶

FIGURE 85-10 **A**, Gross photograph of a pericardial lipoma from a 71-year-old man. **B**, Hematoxylin-eosin staining depicts mature adipocytes in the tumor with associated vascular supply (magnification: 200x).

FIGURE 85-11 A large mass (arrow) in **A** and **B** on the roof of the atrium abutting the aorta was confirmed to be a paraganglioma. LA = left atrium; LV = left ventricle.

Cystic Tumor of the Atrioventricular Node

Because of their location near the atrioventricular node, these cystic tumors (previously called mesothelioma) can manifest varying degrees of heart block or even sudden death.²⁷ Cardiac MRI is particularly useful in the diagnosis of this tumor.²⁸

Paragangliomas

Paragangliomas (also known as extra-adrenal pheochromocytomas) are a highly vascular tumor that may give rise to hypertension and chest pain.^{29,30} The tumor may be located in the pericardial space with no intracardiac extension.³⁰ Paragangliomas are often situated around the roof of the left atrium and aortic root and may involve the cardiac structures.³¹ Tumors originating from the roof of the left atrium are frequently very large and require extensive surgery, including cardiac autotransplantation (**Fig. 85-11**).³¹ Coronary angiography in these patients commonly shows a characteristic “tumor blush” (**Fig. 85-12**).^{29,30}

Other Very Rare Benign Cardiac Tumors

A few very rare reports of hemangioma,^{32,33} neurofibroma, teratoma,³⁴ leiomyoma, and lymphangioma have appeared, but there are not

enough data to summarize the findings expected, and typically these tumors are diagnosed after resection. Complete resection of the tumor is possible with most of the benign primary ones, in contrast to malignant tumors, and the perioperative death rate is low.³⁵

MALIGNANT PRIMARY CARDIAC TUMORS

Common Clinical Manifestations

Malignant primary cardiac tumors commonly cause symptoms by three separate mechanisms: obstruction, embolization, and arrhythmias. Rarely, pericardial invasion and tamponade may be the first manifestation of the disease. Both atrial and ventricular tumors, when large enough, may result in obstructive symptoms and cause syncope, chest pain, dyspnea, or heart failure. The most common initial symptom is dyspnea, followed by chest pain, cough, syncope, hemoptysis, sudden death, fever, embolic events, and cardiac arrhythmias.²¹ Large tumors on the right side, in addition to causing venous congestion, may also limit cardiac filling and result in sudden decreases in intravascular volume, thereby potentially precipitating syncope in these patients. Left-sided cardiac tumors, if large enough, can also impair ventricular filling and lead to syncope or heart failure (**Fig. 85-13**). Unfortunately, approximately 29% of cardiac sarcomas are found to have metastatic disease at initial evaluation, typically in the lung.²¹ Sarcomas, especially left-sided ones, are commonly associated with cardiac embolic events,¹⁹ and arrhythmia can be an important problem as well. A finding of a cardiac mass with pericardial effusion should raise suspicion for a malignant cardiac tumor.³⁶ It might be expected that the pericardial effusion associated with a malignant primary tumor is due to associated pericardial involvement; however, a malignant effusion is not always present.

Useful Investigations

Because of increasing use of CT and better modalities of cardiac imaging, primary cardiac tumors may be identified at an earlier stage. ECG changes are usually nonspecific; however, heart block, ventricular hypertrophy, bundle branch block, atrial flutter, and atrial tachycardia may be present in some cases. Cardiomegaly is a common but nonspecific radiologic finding of cardiac sarcomas.¹⁹ Echocardiography is frequently used for the initial diagnosis of primary cardiac tumors, with transthoracic two-dimensional, three-dimensional, and contrast-enhanced imaging being appropriate techniques. However, transthoracic two-dimensional echocardiography has several well-known limitations: operator experience, lung interference because of pulmonary disease, narrow rib spaces, or unfavorable body habitus. TEE can provide more specific and detailed imaging than possible with two-dimensional echocardiography, especially structures that are more posterior such as the left atrium. Cross-sectional imaging methods, including CT and MRI, have an important role in the evaluation and further assessment of malignant cardiac tumors, especially

FIGURE 85-12 A tumor blush (arrows) is noted on angiography in a patient with a large mediastinal mass.

for evaluation of myocardial invasion (**Fig. 85-14**), involvement of mediastinal structures, tissue characterization (**Fig. 85-15**), and vascularity.³⁷

Sarcomas

Primary cardiac sarcoma constitutes approximately 1% of all soft tissue sarcomas and is the most common malignant primary cardiac tumor.³⁸ The age at diagnosis of cardiac sarcomas ranges from 1 to

76 years, with a mean age of approximately 40 years.^{21,38} Angiosarcomas and unclassified sarcomas account for approximately 76% of all cardiac sarcomas, of which angiosarcomas are the most common.³⁹ Rhabdomyosarcoma is the most common form of cardiac sarcoma in children. Leiomyosarcoma, synovial sarcoma, osteosarcoma, fibrosarcoma, myxoid sarcoma, liposarcoma, mesenchymal sarcoma, neurofibrosarcoma, and malignant fibrous histiocytoma are other cardiac sarcomas observed.^{19,21,39} Angiosarcomas are found predominantly on the right side, whereas osteosarcomas and unclassified sarcomas are found predominantly on the left side of the heart.^{39,40} Pericardial angiosarcomas are extremely rare.³⁶

Treatment

For treatment purposes, complete resection is the optimal goal of surgical treatment.^{19,21,41} Once surgical treatment is completed, adjuvant chemotherapy seems to be prudent, although not widely studied.⁴¹ It is possible that neoadjuvant therapy may be useful, but this is speculative.⁴² The most common chemotherapeutic regimen used for cardiac sarcomas is combined doxorubicin and ifosfamide. A combination of docetaxel and gemcitabine also showed some response in various sarcomas and can be used as an alternative chemotherapeutic regimen.³⁶ Other treatment options include

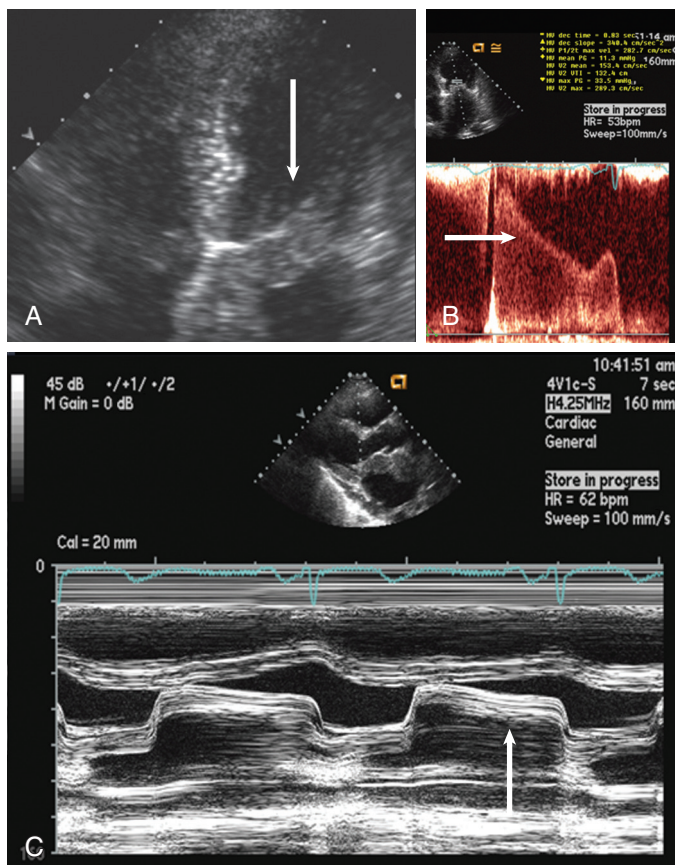

FIGURE 85-13 Echocardiographic Doppler images from a patient with sarcoma evaluated because of heart failure and mitral stenosis. **A**, Four-chamber image with mitral valve thickening (arrow). **B**, Increased velocity across the mitral valve showing stenosis (arrow). **C**, M-mode showing a classic mitral stenosis pattern (arrow).

FIGURE 85-14 T1-weighted cardiac MRI of a left ventricular apical tumor of metastatic alveolar cell sarcoma. Note the indistinct nature of the tumor infiltrating the myocardium (arrow). This is in contrast to the distinct line that classically separates thrombus from myocardium.

FIGURE 85-15 MRI of a left atrial sarcoma. **A**, T2-weighted image demonstrating a large left atrial mass near the anterior leaflet of the mitral valve (arrow). **B**, Brisk enhancement during first-pass perfusion of the mass (arrow) confirms a high degree of blood flow strongly suggestive of an angiosarcoma.

ifosfamide-epirubicin (doxorubicin) and cyclophosphamide, vincristine, doxorubicin, and dacarbazine (CyVADIC).³⁸ Unlike other sarcomas, cardiac sarcomas have a very poor overall prognosis, with a median survival of 6 to 25 months after diagnosis.^{15,20,39} The presence of tumor necrosis and metastases is associated with a poor prognosis,³⁹ as is the presence of a right-sided cardiac sarcoma.⁴³ Sarcomas other than angiosarcomas, sarcomas on the left side of the heart, and completely resected sarcomas seem to have a better prognosis.²¹ At the time of surgical resection, patients with negative surgical margins have better survival.⁴³ Cardiac sarcoma found to be low grade on histologic grading may appear to be associated with better survival, although some reports did not find any significant correlation between histologic grade and survival.^{21,39,44}

Lymphomas

Lymphoma is a type of tumor that can be found primarily in cardiac tissue, but it is generally accompanied by disease elsewhere. It would thus be considered a secondary tumor, although it is possible that no other disease is evident in the body. The classic description of cardiac lymphoma is usually made at autopsy, but again, there may also be other disease manifested elsewhere in lymph tissue.¹⁹ If a diagnosis of cardiac lymphoma is made before autopsy without other organ system involvement, it would be likely that the typical chemotherapy used for lymphoma would be recommended.

SECONDARY CARDIAC TUMORS

The incidence of secondary cardiac tumors at autopsy ranges from 1.7% to 14% (average, 7.1%) in cancer patients and from 0.7% to 3.5% (average, 2.3%) in the general population.¹⁶ In contrast to older series, a significant increase in the incidence of cardiac metastases in cancer patients was noted after 1970, predominately because of improvement in imaging modalities. Cardiac metastases can occur either by direct extension, via the bloodstream or lymphatics, or by intracavitary diffusion through the inferior vena cava (IVC) (**Fig. 85-16**). Pericardial metastasis (69%) is the most common, followed by epicardial (34%), myocardial (32%), and endocardial metastases (5%).⁴⁵ The pericardium is most often involved because of direct invasion by thoracic cancer, including breast and lung cancer. Abdominal and pelvic tumors may reach the right atrium through the IVC. The most common tumor exhibiting this tendency is renal cell carcinoma.³⁶ A recent review suggested that in men, lung cancer is the most frequent cause of cardiac metastasis, followed by esophageal cancer and lymphoma, whereas in women, lung cancer is the most frequent, followed by lymphoma and breast cancer.²⁰ The

symptoms of cardiac metastases are extremely variable and depend on the location of the tumor. Dyspnea, palpitations, syncope, chest pain, and peripheral edema are common clinical findings.^{36,45} Heart failure, cardiac arrhythmias, heart blocks, acute myocardial infarction, myocardial rupture, systemic embolization, and superior vena cava (SVC) syndrome (**Fig. 85-17B**) are other manifestations of cardiac metastases. A new heart murmur or any new ECG finding without clear symptoms in a cancer patient should raise suspicion for cardiac metastases. Typical ECG findings encountered in patients with cardiac metastases are ST-T wave changes (mimicking myocardial ischemia or injury), new atrial fibrillation or flutter, and low voltages, with electrical alternans indicating a significant pericardial effusion. ECG findings of myocardial injury may indicate invasion of the coronary vessels by tumor.⁴⁶

Treatment

Treatment of metastatic cardiac tumors is usually palliative because the overall prognosis is poor, with more than 50% of patients dying within 1 year.³⁶ Palliative radiotherapy and chemotherapy for chemosensitive tumors are recommended, whereas surgical resection is not usually possible.^{16,47} In these patients end-of-life care should be discussed and all efforts made to improve quality of life. In highly selected cases, extraordinary surgical approaches can be attempted, such as autotransplantation, but this is an unusual option. Management of a malignant pericardial effusion is typically individualized in accord with local center experience, and close collaboration between oncology and cardiology is necessary to ensure an optimal treatment plan. Recent data strongly indicate that infusion of selected chemotherapeutic agents may be useful in patients with a malignant pericardial effusion.⁴⁸

DIRECT AND INDIRECT COMPLICATIONS OF NEOPLASIA

Pericardial Effusion

The differential diagnosis of a pericardial effusion in a patient with a known malignancy includes malignant effusion, radiation- or drug-induced pericarditis, idiopathic pericarditis, infectious causes (including tuberculosis and fungal and bacterial infection), or iatrogenic and secondary to procedures. It is estimated that approximately 40% of patients with cancer and a pericardial effusion are found to have either radiation-induced (**see Chapter 69**) or idiopathic effusion and that only a minority actually have malignant effusion.⁴⁹ Drug-induced pericarditis is typically seen after high-dose anthracycline or cyclophosphamide therapy (**see Chapter 69**).

FIGURE 85-16 Renal cell carcinoma. **A**, Renal cell carcinoma invading the IVC. **B**, Renal cell carcinoma invading the right atrium (RA) and prolapsing into the right ventricle (RV). A right radical nephrectomy was performed along with removal of tumor in the RA and IVC.

Cardiac Tamponade

Approximately a third of patients with pericardial involvement will initially be found to have impaired cardiac function, and cardiac compression can progress to tamponade, which demands immediate drainage. Symptoms include chest pain, fever, dyspnea, cough, and peripheral edema. Tamponade without two or more signs of an inflammatory process (typically pain, friction rub, fever, diffuse ST-segment elevation) is more likely to be malignant (2.9-fold increase in risk).⁴⁹ Physical examination, ECG, and chest radiographic findings are generally similar to those of pericardial effusion of any cause. Echocardiography demonstrates the effusion, which is usually large,

FIGURE 85-17 SVC obstruction. **A**, Fast imaging with steady-state precession (FISP) showing a large irregular right atrial mass extending into the SVC (arrow). **B**, Dark blood image showing almost complete obstruction of the SVC from a right atrial mass in a patient with a mediastinal mass and neck and facial swelling (arrow). AO = aorta; RA = right atrium.

although it does not have to be if the fluid has accumulated quickly. However, tamponade can occur with loculated effusions, and in these cases the typical echocardiographic signs may be absent. Acute treatment of tamponade includes careful fluid replacement as a temporizing measure if the patient is believed to be volume depleted with compromised hemodynamics.⁴⁹ Echocardiography-guided pericardiocentesis is required. Fluid should be sent for a full battery of diagnostic tests because as noted, the cause is commonly noncancerous, even in patients with known cancer. If the effusion is malignant, cytologic examination of the pericardial fluid is positive in approximately 85% of patients.

Although no randomized clinical trials using various strategies have been conducted, the risk for recurrence of the effusion appears to be reduced by extended catheter drainage (3 ± 2 days; 11.5% recurrence) as opposed to simple pericardiocentesis.⁴⁸ Recurrence of pericardial effusion can often be treated by repeated pericardiocentesis and extended catheter drainage. Some have used intrapericardial instillation of chemotherapeutic agents or sclerosing agents, but it is not clear that this approach is more effective than extended catheter drainage. Occasionally, percutaneous balloon pericardiotomy or pericardiectomy may be required, but patients with malignant effusions have such a poor prognosis (median survival of 135 days in one series of 275 patients) that invasive procedures should be avoided, if possible. Therapy is directed at the underlying tumor.

Constrictive Pericarditis

Constrictive or effusive-constrictive pericarditis is a late complication of chest irradiation that may be becoming more common because of the longer survival of patients with breast cancer and Hodgkin disease, which is typically treated by chest irradiation. This is covered in detail in [Chapter 71](#).

Superior Vena Cava Syndrome

In the midthird of the mediastinum, the left and right brachiocephalic veins join to form the SVC. The SVC then extends caudally, courses anterior to the right main bronchus, and terminates in the superior aspect of the right atrium. The SVC is joined posteriorly by the azygos vein and runs posterior to and to the right of the ascending aorta. During its course the SVC is adjacent to the right paratracheal, azygous, right hilar, and subcarinal lymph node groups. Blood flow in the venous system is under low pressure and the vessel itself is thin walled. Any inflammatory process in the mediastinum or enlargement of the lymph nodes or ascending aorta can cause the SVC to

be compressed and result in reduced blood flow and eventually complete occlusion ([Fig. 85-18](#)).

Cause/Physiology

SVC syndrome was first described by William Hunter in 1757 in a patient with a syphilitic aneurysm of the ascending aorta. Over time, vascular causes have declined and now the most common cause of SVC syndrome is malignancy, of which lung carcinoma is the most frequent, followed by lymphoma and metastatic cancer.⁵⁰ Malignancy accounts for more than 85% of cases of SVC syndrome.⁵¹ Other causes of SVC syndrome, which are somewhat benign, account for 3% to 15% of cases and include nonmalignant causes such as thrombosis from the use of intravascular devices (e.g., catheters or pacemakers), infection, thymoma, substernal thyroid goiter, and aortic aneurysm.⁵¹ Other possibilities include disease causing systemic vasculitis, such as Behçet disease, and radiation-induced fibrosis.

Clinical Diagnosis

A clinical diagnosis is usually made on the basis of a constellation of symptoms and signs, and a classification system has been proposed.⁵² The development of SVC syndrome is generally insidious, but occasionally it may develop rapidly. The severity of the syndrome depends on the rapidity of onset of the obstruction and its location. The more rapid the onset, the more severe the symptoms because collateral veins do not have time to distend and accommodate the increased blood flow. A typical manifestation consists of facial edema, dyspnea, and cough.^{50,53} Facial edema is seen most frequently; it is worse in the morning and gets better during the day as the patient ambulates. Other symptoms that occur less frequently include stridor, headache, syncope, dizziness, hoarseness, and confusion.^{50,53} Common findings on examination include facial edema, distended neck and chest veins, arm edema, and facial plethora.⁵⁰

Investigations

Investigations depend primarily on whether the underlying cause is known. In a patient with no previous diagnosis, a chest radiograph, CT of the chest, and potentially bronchoscopy may reveal lung cancer as the most common cause. CT is usually very helpful because it provides a detailed evaluation of the venous system and also helps identify the principal causes, such as a neoplasm, thrombosis from central catheters, or infection resulting in sclerosing mediastinitis.⁵⁴ Magnetic resonance venography can be used as an alternative to CT in patients with an allergy to contrast dye or in whom CT cannot be performed for other reasons. Intravenous venography is another option in patients who may not be able to undergo CT.

FIGURE 85-18 Anatomy of SVC syndrome. Lymph nodes may obstruct blood return above the entrance of the azygos vein (**A**) and result in edema of the face, neck, and arms and distended veins in the neck and arms and over the upper part of the chest. Obstruction below the return of the azygos vein (**B**) results in retrograde flow through the azygos via collateral veins to the IVC and in all the symptoms and signs in **A** plus dilation of the veins over the abdomen as well. (Modified from Skatin AT (ed): *Atlas of Diagnostic Oncology*. 3rd ed. Philadelphia, Elsevier Science, 2003.)

Treatment

Treatment is directly related to the underlying cause. In patients with known malignancy, systemic chemotherapy and radiation therapy are typically carried out. If the main cause of SVC obstruction is thrombosis, stent deployment is an attractive option.^{55,56} Surgical bypass of an obstructed SVC is another option, especially if insufficient diagnostic tissue can be obtained by other measures.

Valvular Disease

It is certainly common for cardiac tumors to directly affect valvular structures, depending on the type of tumor, its location and size, and any associated infectious or thrombotic conditions that are associated with the tumor. An additional tumor that classically has an impact on cardiac valvular structures is carcinoid. Patients with carcinoid are at substantial risk for the development of severe tricuspid regurgitation, which may require surgical repair or replacement. The valvular abnormality includes tethering of the leaflets resulting in poor coaptation. It can become a very difficult condition to manage medically and could require surgical intervention (**Fig. 85-19**).⁵⁷

FUTURE DIRECTIONS

The clinical outcome of patients with a primary cardiac tumor depends heavily on early detection and prompt, appropriate treatment. It is a frequent phenomenon that cardiac tumors are discovered only after a patient experiences a period characterized by a confusing constellation of symptoms that are ultimately connected to abnormal findings on an image suggestive of a cardiac tumor. As a result, an advanced stage of disease is already commonly present at the time of diagnosis. Over the last few years the increasing use of imaging modalities (e.g., echocardiography, MRI, and CT) has led to

an increasing number of incidental findings of primary cardiac tumor. However, current imaging techniques can accurately differentiate tumors from other causes of masses seen on imaging only slightly more than 50% of the time. It is hoped that with improvement in echocardiography, CT, and MRI techniques, all cardiac tumors would be identified with a high degree of certainty. There is no non-invasive technique that can identify whether the tumor is benign or malignant, and therefore a pathologic sample is needed in all cases. Improvement in surgical technique has led to minimally invasive approaches, but this still entails general anesthesia and a surgical incision and is the source of major stress for a patient. Continued refinement of surgical tools and approaches will lead to less morbidity and mortality.⁵⁸ Transvenous biopsy of the cardiac mass for pathologic confirmation (under echocardiographic guidance) is done at some centers. Refinement of this technique will enable better sampling in the future. In some centers, PET is routinely used to evaluate for metastatic disease. Currently, no blood tests are available that would point to metastasis.

Better noninvasive imaging of tumor extension is needed because at present only a minority of patients with right-sided heart sarcoma have a pathologically negative margin after resection, and the use of neoadjuvant chemotherapy in selected cases may provide better results, but outcomes need to be reported in a disciplined manner.⁴⁰ All patients should be managed by a multidisciplinary team that includes medical oncologists, radiation oncologists, cardiologists, and cardiac surgeons. Over next few years it is hoped that better targeted therapy will be developed that will inhibit or arrest the malignant proliferating endothelial cells. Cardiac autotransplantation, which was originally performed by Dr. Cooley in 1984, is now a standard practice for complex cases in some centers. With further improvement in surgical techniques, chemotherapy, and radiation therapy, the overall prognosis of patients with cardiac tumors will continue to improve.

Recognition of the importance of psychological stress and emotional factors as potentially modifiable risk factors for cardiovascular disease (CVD) is growing. Psychological stress potentially contributes to CVD at several stages of the disease process, from influencing risk factors for CVD, to affecting the development of atherosclerosis and subclinical CVD, to impairing recovery, prognosis, and quality of life of patients who have survived an acute coronary syndrome.¹

STRESS RESPONSE AND CARDIOVASCULAR DISEASE

The stress response, an adaptive physiologic mechanism that allows the organism to respond to life-threatening situations, results in stimulation of the sympathoadrenal system and the hypothalamic-pituitary-adrenal (HPA) axis with release of cortisol and catecholamines (see Chapter 89). This concept has evolved from a simple model of a “fight or flight” response to threat to better understanding of the more complex interactions of the physical and social environment with the brain and the body involving the neuroendocrine, autonomic, metabolic, and immune systems.² Acute activation of these systems mobilizes energy and prepares the individual for adequate coping with stressors. With chronic exposure to stress, however, repeated attempts at adaptation may result in pathologic perturbation with adverse consequences on hemodynamics, metabolism, inflammation, and immune function.

Psychological factors have been implicated both as triggers of acute coronary events and as promoters of the atherosclerotic process. A number of possible underlying biologic mechanisms have been proposed, including among others, a repeated or sustained increase in blood pressure and heart rate, insulin resistance and other metabolic abnormalities, systemic vascular resistance, autonomic dysregulation, ventricular arrhythmias, and dysregulation of the inflammatory and immune systems (Fig. 86-1). In addition to biologic mechanisms, lifestyle plays an important role inasmuch as

stress, especially in the presence of stress-related disorders such as posttraumatic stress disorder (PTSD) and depression, increases the risk for adverse behavior such as smoking, drug and alcohol abuse, poor eating habits, and lack of adherence to preventive measures and treatment recommendations. However, individual responses to stress vary. Such responses can be modulated by genetic factors and by buffering psychosocial resources, such as social support, optimism, and other personality traits, which represent what is also known as resilience or “psychological reserve capacity.”

METHODOLOGIC ISSUES

Animal models, particularly nonhuman primates, have provided experimental evidence of the adverse cardiovascular effects of chronic stress.³ In humans, however, demonstration of a causal link between stress and CVD has been difficult to prove. From a methodologic standpoint, two major research strategies have been used to study the role of psychological factors on risk for CVD in human populations. The first includes standard epidemiologic methods to examine the relationship between exposure to stressors or other psychological factors and CVD endpoints. The second approach, which provides a more direct mechanistic insight, is to measure cardiovascular responses to a standardized “mental stress test” in the laboratory. Although the effects of experimentally induced stress in the laboratory on the cardiovascular system are well documented, determination of the impact of naturally occurring acute or chronic stressors on CVD by traditional epidemiologic methods has been more challenging to demonstrate. One problem is the definition of exposure. In the field of epidemiology, under the general term of “psychosocial stress,” investigators have included a number of related but not necessarily synonymous constructs that encompass environmental exposures of different sources, intensities, and durations (from acute stressors; to long-term job, financial, or family difficulties; to minor everyday hassles), as well as individuals’ subjective responses to stressors and emotional states. In the mental health fields of

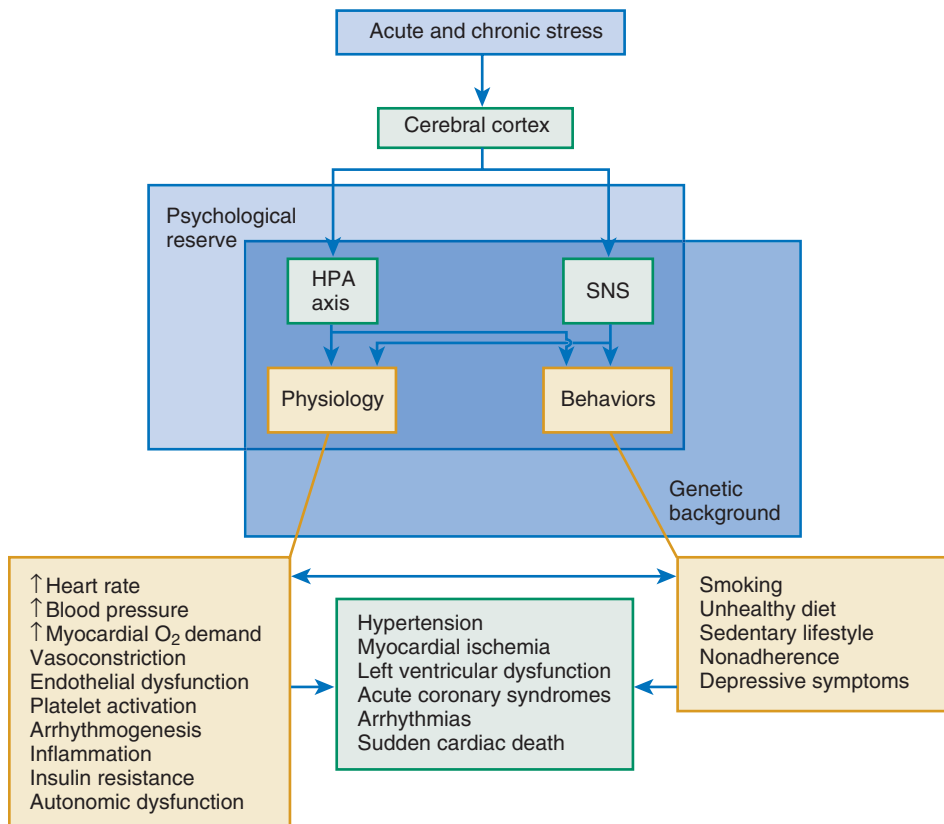

FIGURE 86-1 Potential mechanisms underlying the effects of psychological stress on the cardiovascular system. HPA = hypothalamic-pituitary adrenal axis; SNS = sympathetic nervous system. (Data from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*. 4th ed. Washington, D.C., American Psychiatric Press, 2000.)

psychology and psychiatry, investigators have focused on psychiatric diagnoses of stress-related mental disorders and used a definition of traumatic stress, in its current iteration, as a threat to life or self-integrity associated with intense fear, horror, or helplessness. All these exposures are by definition self-reported and typically retrospective in nature, thus further challenging their accuracy. A related problem is the lack of standardized measures to consistently define and quantify the type and severity of psychological stress. Despite these methodologic challenges, psychosocial factors are increasingly being recognized as important and potentially modifiable risk factors and prognostic indicators for CVD.

OBJECTIVES

The goal of this chapter is to review the epidemiologic and pathophysiologic evidence linking psychological factors to CVD and discuss their clinical relevance and management in the current practice of cardiology. From a classification standpoint, psychological/psychiatric risk factors for CVD can be grouped into four main categories: (1) acute stressful triggers of cardiac events; (2) chronic stressors, including among others, work stress, low socioeconomic status (SES), marital and caregiving stress, and lack of social support; (3) personality traits; and (4) psychiatric diagnoses, including depression and anxiety disorders.

ACUTE STRESS

Stressful and Emotional Triggers of Acute Coronary Events

Many studies, albeit not all, have demonstrated an increase in hospital admissions for acute coronary syndromes after emotionally stressful events such as natural and industrial disasters, terrorist attacks,

and sporting events (see Chapter 53).⁴ During the 1994 Northridge earthquake in the Los Angeles area, hospital admissions for acute myocardial infarction increased 35% in the week after the earthquake relative to the week before. Based on coroners' records, sudden cardiac death increased from an average of 4.6 events per day in the week before the earthquake to 24 events on the day of the earthquake and then fell to 2.7 per day in the next 6 days. Only three of these cases were associated with unusual physical exertion. Coronary deaths tended to be clustered around the epicenter of the earthquake, and there was no increase in non-coronary-related deaths. Although similar data have been reported after other earthquakes, the results are not entirely consistent, possibly because of variations in the timing and season of the earthquakes. Earthquakes occurring in winter and early in the morning are more closely related to cardiac events.

War and terrorist attacks have also been associated with acute coronary events. During the initial phases of the Gulf War in the Tel Aviv area in 1991, for example, the incidence of acute myocardial infarction and sudden death increased. By contrast, the World Trade Center terrorist attack in New York City on September 11, 2001, was not linked to an increase in cardiac events immediately following the attack. However, the

incidence of cardiovascular ailments diagnosed by physicians increased by more than 50% in the following 3 years, thus suggesting a more chronic impact of the attack rather than an acute triggering effect. In addition, ventricular arrhythmias increased by more than twofold in patients with implantable cardioverter-defibrillators (ICDs; see Chapter 36), but only during a period from 3 to 30 days after the event. It is possible that the 9/11 attack, which was covered extensively on television, did not cause generalized acute stress as did other events that posed a direct threat to personal safety but had a more subacute and protracted effect on the population.

The impact of major sports matches on cardiac events among spectators is also well documented. Increases in cardiac events and death are more pronounced in the 2 hours after the start of the matches and affect men more than women.⁵

A limitation of these ecologic studies is lack of information on the individual circumstances surrounding cardiac events, which makes it difficult to rule out alternative explanations. Apart from emotional stress, cardiac events could be triggered by physical exertion (such as running away) or dust and other environmental pollutants. In this respect, studies of emotional triggers at the individual level, in which patients are asked about their experiences before the onset of symptoms, should provide more information. On the other hand, such studies can include only survivors of the acute coronary event and must rely on retrospective assessments of the stressor, which may be affected by recall bias. This latter limitation is mitigated by use of the case crossover design, whereby the risk period before the index cardiac event is compared with a control period in the same individual. By using this method, studies have linked intense episodes of anger, acute work-related stressors, or acute sadness and bereavement to coronary events.⁴ In the Determinants of Myocardial Infarction Onset study, 2.4% of patients reported being very angry or furious in the 2 hours before acute myocardial infarction (see Chapter 51). When compared with a matched control period 24 hours earlier, the odds of acute myocardial infarction developing following acute anger

were increased fourfold. In the SHEEP study, patients who reported a sudden, short-term increase in workload, such as a high-pressure deadline, exhibited a sixfold increase in the odds of myocardial infarction developing during the next 24 hours relative to a control period before the infarction. Acute depressed mood was associated with a 2.5-fold higher odds of acute coronary syndromes in comparison to a control period 24 hours earlier in the same individuals.⁶ Exposure to heavy traffic has also been related to the risk for myocardial infarction, and the time that subjects spend in cars or public transportation is directly related to the risk; in addition to stress, however, pollution and noise may contribute to this effect. Finally, stressful life events have been linked to acute myocardial stunning in susceptible individuals with severe, reversible left ventricular dysfunction. This syndrome is known as takotsubo cardiomyopathy or transient apical ballooning syndrome. The patients, almost all women, show exaggerated stimulation of the sympathetic nervous system as indicated by markedly elevated plasma catecholamine levels.

Potential Mechanisms

A key pathophysiologic event underlying acute coronary events is the progression from a stable plaque to a “vulnerable” plaque. Despite the lack of direct evidence that acute psychological stress causes rupture or erosion of atherosclerotic plaque, acute episodes of stress or intense emotions may trigger acute coronary events in susceptible individuals by affecting plaque stability and disruption through hemodynamic activation (increases in blood pressure and heart rate), increased systemic vascular resistance, coronary vasoconstriction, inflammation, and prothrombotic effects, among others. Triggering usually takes place against a background of advanced atherosclerosis; thus it is considered rare in people without underlying coronary artery disease.⁴

Insights from Studies of Mental Stress

A useful method of assessing the effects of stress and emotion on cardiac function is to measure transient cardiovascular responses to a standardized psychological stress challenge in the laboratory, also known as a “mental stress test,” by using techniques such as mental arithmetic, color naming, public speeches, anger recall, and similar tasks (see Chapter 49). This methodology has the advantage of direct experimental manipulation in which potential confounding factors can be controlled or eliminated and causal factors and their mechanisms directly investigated. However, this approach is necessarily limited to short-term responses to acute stress artificially induced in the laboratory and therefore may lack practical significance. To address this issue, longitudinal studies have investigated the link between mental stress-induced cardiovascular responses and future CVD events. A recent systematic review of this literature showed that greater cardiovascular reactivity to mental stress (defined mostly as acute changes in blood pressure and heart rate) and poor recovery from stress (defined as sustained cardiovascular activation above baseline levels during the post-task period) are associated longitudinally with cardiovascular outcomes, including elevations in blood pressure and CVD events, whereas evidence of an association with atherosclerosis endpoints such as carotid intima-media thickness and coronary artery calcifications is more limited.⁷ Cortisol and catecholamine responses to mental stress have also been related to future hypertension and other CVD endpoints.

Mental Stress–Induced Myocardial Ischemia

In addition to cardiovascular reactivity, an important phenomenon that has been studied in conjunction with mental stress in cardiac patients is mental stress–induced myocardial ischemia. The latter is analogous to ischemia induced by exercise or pharmacologic stress, except that the stimulus is psychological, and it has similar prognostic significance.⁸ It can be induced in one third to two thirds of patients with coronary heart disease. It is typically painless and occurs at lower levels of oxygen demand than does ischemia secondary to

physical exertion. In addition, ischemia induced by mental stress is not generally related to the severity of coronary artery disease. Ischemia may develop with mental stress, but not with exercise or pharmacologic stress, although results vary. Mental stress–induced (but not exercise-induced) myocardial ischemia correlates with ischemia measured in daily life ambulatory monitoring. Thus, mental stress testing could theoretically provide a means for identification of patients vulnerable to myocardial ischemia in everyday life.

Results published to date have indicated that mental stress–induced ischemia is a predictor of a poor prognosis. Several patient series with a follow-up period ranging from 1 to 5 years have found substantial increases, between 70% and threefold, in cardiovascular events, revascularization procedures, and death when comparing cardiac patients with mental stress–induced ischemia with those without, independent of the severity of coronary disease and risk factors for CVD.⁸ Although the samples of patients observed longitudinally to date are relatively small, the overall evidence indicates that myocardial ischemia in response to a standardized mental stress test is at least as prognostically important as exercise-induced ischemia, if not more so.

The hemodynamic responses underlying ischemia triggered by psychological stress are different from those underlying exercise-induced stress. Mental stress–induced ischemia occurs at a lower rate-pressure product than does exercise-induced ischemia in the same patients, although the hemodynamic response tends to be larger in patients with mental stress–induced ischemia than in patients who do not become ischemic. Patients in whom ischemia develops in response to mental stress have an increase in systemic vascular resistance, thus suggesting a rise in afterload caused by peripheral vasoconstriction. By contrast, systemic vascular resistance is decreased by exercise. These effects may be secondary to centrally mediated neurogenic peripheral vasoconstriction; in fact, plasma catecholamine levels increase rapidly with mental stress and correlate with hemodynamic changes.⁹

Abnormal coronary vasoconstriction may develop in some patients with coronary artery disease during mental stress, particularly at points of stenosis, which may cause myocardial ischemia. This effect correlates with the endothelium-dependent response to an infusion of acetylcholine and suggests coronary endothelial dysfunction. Because such vasoconstriction can be reversed by alpha-adrenergic blockade (via intracoronary administration of phentolamine), the sympathetic nervous system appears to play a role.^{8,9}

Mental Stress and Cardiac Electrophysiology

Acute mental stress can also induce cardiac electrical instability, including an increase in T wave alternans and other measures of abnormal cardiac repolarization that have been related to arrhythmogenesis and sudden cardiac death (see Chapter 37).¹⁰

Autonomic dysfunction, along with its effects on cardiac electrophysiology, is another process probably underlying the acute adverse effects of stress on the heart (see Chapter 89). Both sympathetic activation and parasympathetic withdrawal can stimulate arrhythmias and lower the threshold for ventricular fibrillation. Heart rate variability, a measure of the beat-to-beat changes in heart rate as the heart responds to internal and external stimuli, is an accepted non-invasive measure of overall cardiac autonomic function. Reduced heart rate variability predicts coronary heart disease in population studies, as well as mortality, particularly sudden death, in patients following acute myocardial infarction.¹¹ Heart rate variability is reduced during acute mental stress in the laboratory and was found to be decreased during major disasters, such as earthquakes or terrorist attacks, in studies of patients who were undergoing ambulatory electrocardiographic monitoring at the time of the event.⁴ These mechanisms may underlie the connection described between acute stress and life-threatening cardiac arrhythmias and sudden cardiac death.

Mental Stress, Inflammation, and Immunity

The inflammatory and immune pathways are critical to atherogenesis, plaque progression, and thrombus formation. It is well established

that the immune system responds acutely to psychological stress. Noradrenaline-dependent adrenergic stimulation as a result of stress-induced activation of the sympathetic nervous system activates the nuclear transcription factor kappa B (NF- κ B) in circulating monocytes, which results in initiation of the inflammatory cascade. Parasympathetic stimulation has the reverse effect: inhibition of NF- κ B activation. Consistent with these biologic effects, mental stress triggers robust increases in circulating inflammatory biomarkers, in particular, interleukin-6 and interleukin-1 β .¹² Impaired poststress cardiovascular recovery after mental stress is also associated with sustained inflammatory and hemostatic responses. However, little prospective information is presently available to link inflammatory responses to an acute stress challenge with future cardiovascular endpoints.

Acute Stress and Cardiovascular Disease: Clinical Implications

The clinical significance of acute emotional triggers of cardiac events has not been clearly established. Although the relative risk associated with acute stress is substantial, the absolute risk is smaller given that these events are relatively uncommon. Accordingly, the population attributable risk (i.e., the reduction in disease that would be observed if the risk factor were eliminated entirely) is also not large ($\approx 4\%$), but it is fairly similar to that of other acute triggers of coronary events such as physical exertion, heavy traffic, or excessive alcohol consumption.¹³ Although it has been argued that programs to increase awareness of psychological triggers among clinicians and the public would be beneficial, such programs in general lack evaluation. Whether therapies for prevention of CVD, such as aspirin, beta blockers, statins, and angiotensin-converting enzyme inhibitors, also protect against the harmful effects of emotional triggers is similarly not known.

CHRONIC STRESS

Common chronic, or long-term, stressors in the general population include factors such as work-related stressors, financial difficulties or low SES, marital/caregiving stress, and low social support. Each of these factors has been evaluated extensively in relation to cardiovascular risk. A potential problem with this literature is that many of these exposures may be correlated with each other over the lifetime whereas individual studies have typically examined single factors without considering cumulative stress exposure from multiple sources. Although a few studies have included more general measures of perceived stress, they were not often specific enough to measure objective external exposure to stressors and are likely to be influenced by individual characteristics such as personality traits and emotional problems.

Work-Related Stress

Work stress has been studied extensively for its potential adverse cardiovascular effects. Two dominant models of work stress that have been associated with risk for CVD include the “job strain” model developed by Karasek and Theorell and the “effort-reward imbalance” model by Siegrist.¹⁴ The job strain model postulates that high work demands in combination with low control produce stress because workers in low-control jobs cannot moderate work pressure by organizing their time or by other means. The highest risk applies to situations of high demand, low control, and low social support at work. According to the effort-reward imbalance model, stress derives from a mismatch between high workload, such as long working hours, and low payback in terms of income, job security, job status, or other forms of recognition. Other less well-studied sources of stress in the workplace include unfair treatment and other forms of organizational injustice, job insecurity, and conflicts with coworkers. Recent systematic reviews have found a significant increase in the risk for CVD in various work stress models.^{14,15} In these pooled analyses, job

strain was associated with a 40% increased risk for CVD, whereas imbalance between effort and reward was associated with a 60% increased risk for CVD.

In general, study results linking job stress to CVD have been stronger for men than for women. It is possible that stress in other life domains, such as family and social relationships, may be more important for women than job-related stress.¹⁶ It should be noted, however, that few studies are available on female samples. In addition, because many study cohorts have included working populations, they may have been too young to capture cardiovascular events among women. Finally, these studies have not typically included information on part-time work, which may be more frequent in women.

Most studies of work stress and CVD have examined initially healthy populations. Studies of patients with established coronary disease are fewer. In a Canadian study, job strain was associated with a twofold increase in risk for recurrent events among patients returning to work after a myocardial infarction.¹⁷ Similarly, in a Swedish cohort, a combined outcome of cardiac death and recurrent myocardial infarction was 70% more frequent in patients with high job strain than in those with low job strain.¹⁸ Because most studies have included predominantly male worker populations, data specific to women with CVD are limited. However, as for populations initially free of CVD, results generally appear weaker in women, even when women who work full-time outside the home were considered.

Marital and Caregiving Stress

Although work stress has been studied primarily in men, marital and caregiving stress has been studied primarily in women. In the Stockholm Female Coronary Risk Study, women who suffered a myocardial infarction and reported marital stress had an almost threefold higher risk for recurrent cardiac events than did women with less marital stress after adjusting for other risk factors.¹⁶ However, few studies are available on this dimension of chronic stress, and data on male populations are limited.

Caregiving for an ill family member is common, with approximately 12% of Americans older than 45 years reporting caregiving responsibilities. High caregiving stress has been associated with a variety of poor physical and psychological outcomes, including higher risk for CVD and mortality. In the Nurses' Health Study, caregiving for an ill or disabled spouse was associated with an almost twofold increased risk for coronary events after adjusting for other risk factors. Similarly, in the Caregiver Health Effects Study, caregiving was associated with a 63% higher adjusted risk for mortality. In the REGARDS (REasons for Geographic and Racial Differences in Stroke) study, high caregiving strain was associated with a 23% higher risk for stroke, an effect that was larger in black American men.¹⁹ The adverse effects of caregiving, however, primarily apply only to caregivers who report psychological strain or distress; caregivers not experiencing strain do not have elevated risk.

Low Socioeconomic Status

SES is generally defined by one or a combination of interrelated factors such as occupational status, economic resources, education, and social class. Area-based SES measures, including census blocks or zip codes and other composite measures of neighborhood impoverishment, are increasingly becoming popular as SES measures because they correlate well with individual SES measures and can be used when the latter are not available.

The existence of a social gradient in health and disease has long been recognized. Beginning many decades ago, the Whitehall Study of British Civil Servants reported that even among people who have access to health care and are not poor, there is a social gradient in mortality and morbidity, including CVD, from the bottom to the top of society.²⁰ Such results have been confirmed in many other contexts, including the United States.

Even in patients with suspected or confirmed CVD, disparities in outcome throughout the SES spectrum exist. In a U.S. study of more than 30,000 patients referred for cardiac stress testing, lower SES was

associated with higher mortality, impaired exercise capacity, and abnormal heart rate recovery.²¹ Similarly, in a Canadian population with universal access to health care, lower household income correlated with significantly higher severity of coronary atherosclerosis in diabetic patients referred for cardiac catheterization.²² Low SES is accompanied by poorer health habits and more unfavorable standard risk factors for CVD, such as hypertension, obesity, smoking, sedentary lifestyle, and unhealthy diet, which, however, only partially account for the CVD gradient attributable to social class.²³ Many adverse psychosocial characteristics are also related to lower SES, including financial hardship, poorer housing, neighborhood status, social discrimination and isolation, depression, and adverse working conditions. Thus low SES can be viewed as a composite of chronic stressors that may result in adverse behavioral and physiological consequences. Lower access to preventive medical care may also play a role in societies, such as the United States, that do not have universal health care systems.

HPA axis and autonomic dysfunction is observed as SES declines, which may increase the risk for central obesity and metabolic risk factors. The Whitehall II study, for example, described a close relationship between lower social position and increased prevalence of the components of metabolic syndrome, an association that was only partially explained by health behavior.²³ Disturbances in neuroendocrine and cardiac autonomic activity, compatible with activation of neuroendocrine stress axes, were also noted in subjects with metabolic syndrome and those with lower SES status. Notably, psychosocial factors (SES- and job-related stress) explained a large proportion of the association between adrenal/autonomic disturbances and metabolic syndrome.

Adverse Childhood Experiences

Adverse childhood experiences, sometimes referred to as “early life stress,” are commonly defined as various forms of maltreatment in childhood, such as verbal, physical, and sexual abuse. Some definitions also include indicators of family dysfunction, such as domestic violence or the presence of family members who are drug addicted, incarcerated, or mentally ill. Adverse childhood experiences are quite prevalent in the general population. In a recent national survey of adults, approximately one quarter (26%) reported verbal abuse in childhood; 15%, physical abuse; and 12%, sexual abuse.²⁴ Adverse childhood experiences have been linked to a range of adverse health outcomes in adulthood, including substance abuse, depression, PTSD, CVD, and premature mortality.²⁵ A recent meta-analysis confirmed a link between childhood maltreatment and a number of medical outcomes in adulthood, including CVD.²⁶ Despite heterogeneity of effects across studies, the association is seen both when abuse is measured by self-report and when it is measured objectively.

In terms of mechanisms, although the literature is limited by many studies being cross-sectional or retrospective, the bulk of the evidence links adverse childhood experiences to enduring changes in the nervous, endocrine, and immune systems.²⁵ A history of childhood maltreatment has been associated with smaller volumes of the prefrontal cortex and the hippocampus, greater activation of the HPA axis during stress, and elevated inflammation.²⁷ These changes persist in adulthood, thus providing evidence for an enduring effect of early life stress on physical health. For example, a prospective study linked childhood maltreatment to adult inflammation.²⁸ Maltreated children showed higher inflammation 20 years later, which persisted after accounting for other childhood exposure and health behavior.

Social Isolation, Loneliness, and Lack of Support

Social isolation and loneliness appear to be increasingly common; for example, between 1985 and 2004, the number of people with no one to discuss important matters tripled to 25%.²⁹ The size, quality, and perceived adequacy of a person's social contacts have all been

related to CVD and total mortality. Social relationships may improve health in a variety of ways, including provision of instrumental and emotional support and encouragement toward a healthy lifestyle and health care seeking. Emotional support may also buffer the adverse effects of psychological stressors. Reverse causation is possible as well, however, in that individuals who are ill or otherwise at risk may be less socially engaged.

Despite scientific interest in these constructs, there is little theoretical integration of their various dimensions and little consensus on measurements and mechanisms. Although a number of population studies have shown elevated risk for CVD in socially isolated individuals or those with low levels of support, the results are not consistent. A recent meta-analysis found a 50% increase in the odds of survival in persons with stronger social relationships, but there was significant heterogeneity in individual study results.³⁰ Another systematic review revealed a similar pooled effect size for coronary disease (51% increase) related to social isolation and loneliness.¹

In cardiac patients, factors such as living alone, lacking a confidant, being socially isolated, or perceiving low support have all been linked to poorer prognosis. In a systematic review of patient populations with coronary disease, such indicators of low social support showed pooled estimates of relative risk ranging from 1.6 to 1.7 for subsequent CVD events and mortality.³¹ These associations generally persisted after adjusting for lifestyle behavior and disease severity. Thus, the instrumental and emotional aspects of social contacts may be beneficial for high-risk individuals such as cardiac patients.

Perceived General Stress

Some studies have examined the relationship between nonspecific perceived stress during daily life, sometimes referred to as “psychological distress” or “general stress,” and the onset or exacerbation of CVD. In general, these studies have been inconsistent in their definition of stress, which in addition to daily stressful exposures of various intensity in some studies, included mood, anxiety and neuroticism symptoms, and personality traits in other studies. Not surprisingly, findings have been conflicting in terms of effect size, statistical significance, and subgroup results. For example, the Copenhagen City Heart Study found a relative risk of 2.6 for incident ischemic heart disease in response to “high stress” versus “low stress” in men younger than 55 years, but no association was found in women and older men.³² One of the largest studies to date addressing this question is the INTERHEART study, an international case-control study consisting of 15,152 patients with myocardial infarction and 14,820 controls from 52 countries worldwide. This study included brief assessments of depression, locus of control, perceived stress at home or work, financial stress, and adverse life events. High general stress at home or work was significantly associated with myocardial infarction, with an odds ratio of 1.5 after adjusting for geographic region, age, sex, and smoking. This estimate was similar across regions, ethnic groups, and sex. Permanent general stress, which is the highest severity level of the general stress classification, had an odds ratio of 2.2 for myocardial infarction. The study also evaluated a composite score of psychosocial risk factors, including stress at work and at home, financial strain, lack of control, stressful life events, and depression, and found that in terms of both odds ratio and population attributable risk, the independent risk associated with psychosocial factors was comparable to that of standard CVD risk factors.

A recent study of more than 60,000 people from the general population in England examined a measure of “distress” that included symptoms of anxiety, depression, social dysfunction, and loss of confidence in relation to mortality from different causes.³³ After a follow-up of approximately 8 years, psychological distress was associated with deaths from all causes in a dose-response pattern, independent of somatic comorbidity and behavioral and socioeconomic factors. The association was particularly robust for cardiovascular deaths and deaths from external causes and was evident even with less severe levels of distress.

Chronic Stress and Cardiovascular Disease: Clinical Implications

Few data are available on the potential clinical usefulness of incorporating measures of chronic stress for CVD risk prediction, for prognostic assessment, or for the clinical management of cardiac patients. Some studies, however, suggest that consideration of factors such as work-related stress or measures of SES in addition to standard risk factors may improve risk prediction. For example, information on long working hours may improve the prediction of coronary heart disease in otherwise low-risk working individuals.³⁴ In a nationally representative population in the United Kingdom, incorporating an index of social deprivation based on census data with other risk factors into a clinical algorithm for CVD risk prediction (the QRISK2) showed improved accuracy in the identification of people at high risk.³⁵ It has been argued that ignoring the independent contribution of SES to the risk for CVD may exacerbate health disparities by underestimating risk in the socially disadvantaged.³⁶ In the United States, no established algorithm currently exists that incorporates SES or measures of chronic stress for assessment of risk for CVD.

Current European guidelines on CVD prevention recommend assessment of psychosocial stressors via standardized instruments or even a brief questionnaire and recommend tailored clinical management of these factors in individual patients (class of recommendation, IIa; level of evidence, B).³⁷ No such recommendations are included in prevention guidelines by the American Heart Association or the American College of Cardiology.

PERSONALITY TRAITS

Anger and Hostility

The potentially harmful effects of anger on health have been suspected since ancient times. Not surprisingly then, anger, hostility, and related constructs have received considerable attention as potential risk factors for CVD. Despite being different constructs, anger and hostility are often used interchangeably, and their interconnection is poorly defined. Hostility is a personality/cognitive trait characterized by a negative attitude toward others. It is one of the dimensions of a type A personality, which was believed, in early research, to be a risk factor for CVD, a relationship not supported by later investigation. Anger is an emotional state characterized by feelings ranging from mild irritation to intense fury or rage toward others. A recent meta-analysis found substantial heterogeneity of results, with half to two thirds of the studies failing to find a significant association between anger or hostility and coronary heart disease.³⁸ The summary combined estimate for anger and hostility indicated a modest, but significant 19% increase in the incidence of coronary heart disease in initially healthy populations and a 24% increase in recurrent coronary heart disease events in patients with preexisting coronary heart disease. However, studies of higher quality tended to show smaller and nonsignificant effects. The risk associated with anger and hostility appears to be more marked in men and is in large part explained by behavioral factors such as smoking and physical activity.³⁸

Type D Personality

Type D (or “distressed”) personality, a concept first introduced in 1995 by Denollet and colleagues, is a personality type that combines negative affectivity and social inhibition.³⁹ It describes individuals who tend to experience negative emotions (dysphoria, tension, worry) and at the same time are inhibited in their expression of emotions, thoughts, and behavior in a social context. These investigators were able to link this construct to adverse cardiovascular outcomes and total death in a number of studies of patients with CVD. Because type D personality is related to other psychosocial characteristics (hostility, anger, depression, and social isolation), its interconnection with and independence from these other factors need more

evaluation. However, this personality type appears to be a predictor even after depression and other psychosocial stressors are accounted for. These authors propose that it is the combination of these two traits (negative affect and social inhibition) that is damaging rather than either one alone.

Personality Traits and Cardiovascular Disease: Clinical Implications

Although the literature on personality traits and CVD dates back many decades, consistency of results has been an issue. Particularly for anger and hostility, the effect size appears to be small, and whether personality traits provide predictive and prognostic information above and beyond other better established psychosocial factors and traditional CVD risk factors needs more evaluation. Finally, it is unclear to what extent these personality traits may be modifiable by interventions. Because of these issues, the clinical significance of these observations is not well established.

DEPRESSION AND ANXIETY SYMPTOMS AND PSYCHIATRIC DISORDERS

Depression and anxiety differ from other psychological factors considered in this chapter in that in addition to being common in the population at a subthreshold level, they are also diagnosable psychiatric disorders and therefore amenable to drug treatment or other types of clinical management. Much of the evidence linking depression and anxiety disorders to risk for CVD, however, is derived from epidemiologic studies that used self-reported symptom scales rather than psychiatric diagnoses. Nonetheless, studies have found correlations between anxiety and depressive symptoms above specific cut points and psychiatric diagnoses of anxiety and depressive disorders based on clinical assessments such as the Structured Clinical Interview for the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revised (DSM-IV-TR), commonly known as the SCID. Thus the use of self-reported measures of depression and anxiety has clinical usefulness in studying the relationship between CVD and depressive and anxiety disorders.

Depressive Symptoms and Major Depression

In the cardiovascular literature, the study of depression has included a variety of entities, from depressive symptoms measured with a host of different symptom scales, to a clinical diagnosis of depression, to different depression subtypes. Depression may be a contributing factor to the development or progression of CVD or may be secondary to the presence of CVD, or common mechanisms may result in the development of both depression and CVD.

As defined by the DSM-IV-TR, major depression is characterized by depressed mood or anhedonia (inability to experience pleasure from normally enjoyable activities) for at least 2 weeks, accompanied by significant functional impairment and additional somatic or cognitive symptoms, for example, problems with appetite and sleeping and feelings of hopelessness or worthlessness (Fig. 86-2). Depressive symptom scales typically capture various combinations of cognitive and somatic symptoms of depression and can provide an assessment of the severity of depressive symptoms, for example, by counting the number of symptoms present. Although no symptom scale can provide a clinical diagnosis of major depression, many have validated cut points that approximate a diagnosis of major depression.

Depression is a highly prevalent condition and a growing global problem. By 2030, depression is projected to be the second leading cause of disability worldwide (after human immunodeficiency virus infection/acquired immunodeficiency syndrome) and the number one cause of disability in high-income countries. Depression is three times more common in cardiac patients than in the general population, and 15% to 30% of cardiac patients have clinically significant depression.

DSM-IV-TR Criteria for Major Depression

- A. At least five of the following symptoms have been present during the same 2-week period and represent a change from previous functioning, and at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.
 1. Depressed mood most of the day, almost every day, as indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful).
 2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, almost every day (as indicated either by subjective account or observation made by others).
 3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite almost every day.
 4. Insomnia or hypersomnia almost every day.
 5. Psychomotor agitation or retardation almost every day (observable by others, not merely subjective feelings of restlessness or being slowed down).
 6. Fatigue or loss of energy almost every day.
 7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) almost every day (not merely self-reproach or guilt for being sick).
 8. Diminished ability to think or concentrate, or indecisiveness, almost every day (either by subjective account or as observed by others).
 9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or specific plan for committing suicide.
- B. The symptoms do not meet the criteria for a mixed episode.
- C. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- D. The symptoms are not due to the direct physiologic effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).
- E. The symptoms are not better accounted for by bereavement (i.e., after the loss of a loved one), and the symptoms persist for longer than 2 months or are characterized by marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation.

FIGURE 86-2 DSM-IV-TR criteria for major depression. (Data from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*. 4th ed. Washington, D.C., American Psychiatric Press, 2000.)

The prevalence of depression is higher in women than in men; among myocardial infarction patients the prevalence of depression is particularly high, about 40%, in younger women (<60 years old).⁴⁰

The higher prevalence of depression in cardiac patients may reflect the well-known fact that depression can be secondary to medical illness, such as coronary heart disease. It may also reflect the fact that depression is a risk factor for coronary disease. Many meta-analyses have provided evidence of an association between clinical depression (or depressive symptoms) and risk for CVD, both in individuals initially free of heart disease and in a variety of heart disease patient populations, including those with acute coronary syndromes, congestive heart failure, stable coronary heart disease, and post-coronary bypass surgery status.⁴¹ However, individual studies have produced heterogeneous risk estimates and have varied in their ability to adjust for potential confounding factors such as smoking, physical inactivity, and severity of coronary heart disease. In individuals initially free of heart disease, a recent meta-analysis reported a pooled unadjusted relative risk for future coronary events of 1.8 (95% confidence interval, 1.5 to 2.2) when comparing depressed with nondepressed persons.⁴¹ In patients with coronary heart disease, the pooled relative risk for recurrent events or mortality was the same: 1.8 (95% confidence interval, 1.5 to 2.2). However, adjustment for disease severity attenuated the association in patients with coronary heart disease by almost 50%, thus suggesting possible reverse causation (severe coronary heart disease leading to depression).

Although most studies have examined depressive symptoms rather than major depression, those that did consider major depression tended to find larger risk estimates than those assessing symptom scales did. Yet there is evidence for a gradient of risk linking the level of depressive symptoms to the likelihood for adverse cardiac events, beginning at relatively low levels of depressive symptoms.

Recent literature has also suggested that depression is a heterogeneous condition in its relationship with CVD and that specific subtypes may be more important, such as new-onset depression after acute coronary syndromes, treatment-resistant depression, or somatic depressive symptoms as opposed to cognitive symptoms. However, there is no clear consensus on whether these different phenotypes carry variations in risk.⁴²

Potential Mechanisms

Depression is associated with other cardiovascular risk factors, including smoking, sedentary lifestyle, obesity, diabetes, and hypertension, but many studies, although not all, have shown an independent effect of depression on cardiac outcomes after adjusting for these factors. In cardiac patients, depression is also associated with the severity of functional impairment, which may lead to a decrement in physical activity or self-care, which in turn could accelerate progression of coronary heart disease. In addition, depressed patients show lower adherence to medication regimens, modification of lifestyle risk factors, and cardiac rehabilitation. Thus, depression may affect cardiac outcomes via behavioral mechanisms involving healthy lifestyle, delay in seeking treatment, and nonadherence to secondary prevention.⁴³

In general, depression is characterized by overactivity of the HPA axis and the sympathoadrenal system resembling neuroendocrine responses to stress, with increased or prolonged release of cortisol and norepinephrine and disruption of normal circadian patterns. These abnormalities may lead to repeated or sustained elevations in blood pressure, heart rate, and plasma glucose and lipids. Depressed individuals also show reduced parasympathetic flow. Heart rate variability, a noninvasive measure of cardiac autonomic function, is lower in depressed patients.⁴⁴ Other indications of autonomic dysfunction in depressed cardiac patients include an increased heart rate response to orthostatic challenge, an abnormal heart rate response to premature ventricular contractions, and abnormal ventricular repolarization. All these factors predict mortality in cardiac patients.

Enhanced platelet activity in depression has been proposed as another potential link between depression and cardiac events, but the data are limited and the results mixed. Another postulated mechanism is increased inflammation. Many studies have shown an association between depression and elevated levels of acute-phase proteins, such as C-reactive protein, and inflammatory cytokines, such as interleukin-6, in subjects with and without CVD. However, results in CVD patients are somewhat inconsistent, and to date there is no clear evidence that inflammation is a mechanism in the link between depression and cardiovascular outcomes.

Finally, growing evidence suggests that depression and CVD may be different phenotypic expressions of the same genetic substrate.⁴⁵ Genetic pleiotropy, however, does not eliminate other causal possibilities, for example, certain CVD genes causing depression and depression, in turn, accelerating CVD.

Clinical Implications

Despite the established comorbidity between depression and physical illness, particularly CVD, less than half of depressed medical

patients are recognized by their physicians as being depressed.⁴⁶ During an admission for acute myocardial infarction, less than 15% of patients with depression are identified. In 2008, an advisory statement by the American Heart Association recommended routine screening for depression in patients with coronary heart disease.⁴⁷ This advisory suggested the use of quick case-finding instruments to improve the ability of non-mental health specialists to detect and manage depression. There is no consensus, however, that such recommendation is warranted, and some have argued that it may be premature.⁴⁸ One reason for this uncertainty is lack of demonstration that systematic screening for depression translates into better management of depression and better outcomes in cardiac patients.⁴⁹ Investigation in this area has been limited, however, with few randomized clinical trials of treatment and screening of depression. Because the literature overall points to depression as a risk factor and prognostic factor for CVD, it is reasonable for clinicians to evaluate depression as they would any other risk factor such as smoking and diabetes.⁵⁰

According to the current American Heart Association/American College of Cardiology guidelines for secondary prevention in patients with CVD, screening for depression is reasonable if patients have access to case management in collaboration with their primary care physician and mental health specialist (class IIa; level of evidence, B). Treatment of depression is reasonable for its clinical benefits other than improving outcomes of CVD (class IIb; level of evidence, C).⁵¹ Patients with severe depressive symptoms or a clinical diagnosis of depression should be evaluated in concert with a mental health specialist as needed.

Anxiety Symptoms and Anxiety Disorders

As for depression, a mix of conditions labeled as “anxiety” have been studied in relation to CVD, from psychiatric diagnoses to subthreshold symptoms that are common in the general population and can be assessed with symptom scales. The anxiety disorders as currently classified include generalized anxiety disorder, phobic disorder, panic disorder with and without agoraphobia, obsessive-compulsive disorder (OCD), and PTSD. Recent surveys have found that as many as 18% of Americans may be affected by one or more anxiety disorders. Patients with anxiety disorders have symptoms in common, including excessive rumination, worrying, apprehension, and fear about future real or imagined events. Other symptoms are characteristic of specific anxiety disorders, for example, increased startle reactions in PTSD or fear of contamination in OCD. Some authors have argued for a conceptualization of trauma spectrum disorders that would include, in addition to PTSD and depression, dissociative disorders, borderline personality disorder, and substance abuse disorders. This conceptualization may be relevant to the discussion of CVD and psychiatric disorders if the common underlying variable that increases risk for CVD is exposure to psychological trauma.

Like depression, most studies examining the relationship between anxiety and CVD have considered anxiety symptom scales rather than a clinical diagnosis of anxiety disorder. Results, however, are inconsistent, and about half the studies failed to find a significant association between anxiety and risk for CVD, both in initially healthy populations and in patients with CVD. A recent meta-analysis pooled the results of approximately 20 longitudinal studies and found a modest (26%) increased risk for incident coronary disease and a 48% increased risk for cardiac death in persons with anxiety, independent of demographic variables, biologic risk factors, and health behavior.⁵² This meta-analysis confirmed substantial heterogeneity across studies. Like other psychosocial factors, the inconsistencies may be due to variations in the measurement of anxiety and the fact that symptom scales may not discriminate among different anxiety disorders, which may vary in their severity and biologic substrate.

Posttraumatic Stress Disorder

Emerging evidence indicates that PTSD, another anxiety disorder, may increase the risk for CVD. PTSD is by definition linked to a traumatic event, which is defined by the DSM-IV-TR as a threat to life or

self-integrity accompanied by intense fear, horror, or helplessness. Causes of PTSD include, for example, rape, combat trauma, motor vehicle accidents, assault, and childhood abuse. Contrary to popular belief, combat trauma is not the most common cause of PTSD; there are about 10 times as many nonveterans with PTSD as veterans. It should be noted that previous versions of the diagnosis had a stricter definition of trauma as something beyond the range of normal human experience, and future versions will probably loosen the criteria further so that most of the population will be categorized as having been exposed.

Three groups of PTSD symptoms are recognized, namely, intrusions (e.g., recurrent memories of the traumatic event that the patient cannot control), avoidance (avoiding things that would remind the person of the trauma), and hypervigilance (e.g., trouble falling or staying asleep, irritability, outbursts of anger, and difficulty concentrating). To meet criteria for the diagnosis according to the DSM-IV-TR, there is a requirement to have one symptom from the first group, three from the second, and two from the third, as well as significant impairment in work and/or social function (**Fig. 86-3**). The duration of symptoms must be at least 1 month; if symptoms have been present for less than a month, the patient may meet the criteria for acute stress disorder (not covered here), which frequently progresses to PTSD. Persons with PTSD may also have difficulties with employment and relationships and increased rates of depression and substance abuse.

More than half of Americans will experience a traumatic event at some time in their lives. It is therefore not surprising that PTSD is relatively common in the general population, with a lifetime prevalence of 10% to 12% in women and 5% to 6% in men. The lifetime prevalence of PTSD in combat veterans is 15% to 19%. In about half the cases, PTSD becomes a chronic condition that can last for years.

Many physical health problems have been noted in patients with PTSD, especially cardiovascular symptoms, but most studies to date are cross-sectional and have other methodologic limitations.⁵³ A few recent longitudinal studies have mostly confirmed a relationship between PTSD and CVD, but they have focused on PTSD symptoms rather than a diagnosis of PTSD. Thus, the data available suggest a relationship between PTSD and increased risk for CVD, but more research is needed.

PTSD can also be a consequence of an acute coronary syndrome, which occurs in approximately one in every eight patients. PTSD secondary to acute coronary syndromes is associated with approximately double the risk for recurrent cardiac events and mortality.⁵⁴ Both acute cardiac events and PTSD are associated with sympathetic activation and elevated proinflammatory cytokines; it is possible that these additive effects are damaging to the heart. PTSD is especially prevalent in survivors of out-of-hospital cardiac arrest, with a prevalence ranging from 27% to 38%. Among patients with an ICD, a significant proportion of whom have survived a cardiac arrest or myocardial infarction, PTSD has been associated with a threefold increased risk for subsequent mortality.⁵⁵

Clinical Implications

Anxiety disorders are highly prevalent, approximately as common as hypertension. Regardless of their high frequency and possible cardiac risk, anxiety disorders are associated with considerable disability and impaired quality of life. Anxiety often coexists with depression; in this case, the corresponding impact on quality of life is even higher. Among the anxiety disorders, PTSD is emerging as a risk factor for CVD. Because PTSD by definition is closely related to psychological trauma, the effect of PTSD on CVD could be a reflection of the long-lasting effects of exposure to trauma on physical health.

Given that approximately 1½ million patients are discharged from U.S. hospitals each year with a diagnosis of acute coronary syndrome, clinically significant PTSD symptoms could develop in more than 150,000 patients as a result (**see Chapters 51 to 54**).⁵⁴ Thus, PTSD could contribute substantially to repeated hospitalization, mortality, and increased health care costs for cardiac patients. Primary care patients in the Veterans Administration system are routinely screened for PTSD with questionnaires such as the four-item PC-PTSD (Primary Care PTSD Screener). Similar to depression, however, the usefulness

DSM-IV-TR Criteria for Posttraumatic Stress Disorder

- A. The person has been exposed to a traumatic event in which both of the following were present:**
1. The person experienced, witnessed, or was confronted with an event that involved actual or threatened death or serious injury or a threat to the physical integrity of self or others.
 2. The person's response involved intense fear, helplessness, or horror. Note: In children this may be expressed, instead, by disorganized or agitated behavior.
- B. The traumatic event is persistently reexperienced in one (or more) of the following ways:**
1. Recurrent and intrusive distressing recollections of the event, including images, thoughts, or perceptions. Note: In young children, repetitive play may occur in which themes or aspects of the trauma are expressed.
 2. Recurrent distressing dreams of the event. Note: In children there may be frightening dreams without recognizable content.
 3. Acting or feeling as though the traumatic event were recurring (includes a sense of reliving the experience, illusions, hallucinations, and dissociative flashback episodes, including those that occur on awakening or when intoxicated). Note: In young children, trauma-specific reenactment may occur.
 4. Intense psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event.
 5. Physiologic reactivity on exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event.
- C. Persistent avoidance of stimuli associated with trauma and numbing of general responsiveness (not present before the trauma), as indicated by three (or more) of the following:**
1. Efforts to avoid thoughts, feelings, or conversations associated with the trauma
 2. Efforts to avoid activities, places, or people that arouse recollections of the trauma
 3. Inability to recall an important aspect of the trauma
 4. Markedly diminished interest or participation in significant activities
 5. Feeling of detachment or estrangement from others
 6. Restricted range of affect (e.g., unable to have love feelings)
 7. Sense of a foreshortened future (e.g., does not expect to have a career, marriage, children, or a normal life span)
- D. Persistent symptoms of increased arousal (not present before the trauma), as indicated by two (or more) of the following:**
1. Difficulty falling or staying asleep
 2. Irritability or outbursts of anger
 3. Difficulty concentrating
 4. Hypervigilance
 5. Exaggerated startle response
- E. Duration of the disturbance (symptoms in criteria B, C, and D) is longer than 1 month.**
- F. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.**

FIGURE 86-3 DSM-IV-TR criteria for PTSD.

of routinely screening for anxiety and PTSD symptoms in cardiac patients is unknown, particularly in the nonveteran population at large (see also the next section). Pharmacologic and psychotherapy approaches to the treatment of PTSD and other anxiety disorders are available,⁵⁶ and thus recognition and treatment of these disorders could have at least theoretical benefits for symptomatic and functional improvement. The benefit in reducing risk for CVD, however, is untested.

EVALUATION AND MANAGEMENT OF PSYCHOLOGICAL AND PSYCHIATRIC CONDITIONS IN CARDIAC PATIENTS

General Considerations

Recognition of psychological and psychiatric factors should be considered in the management of cardiac patients, not only because

these conditions are prevalent and affect patients' quality of life but also because they act as barriers to treatment adherence, follow-up care, and improved lifestyle, in addition to affecting patient well-being (see [Chapter 54](#)). Yet psychological and psychiatric conditions are less likely than traditional CVD risk factors to be recognized and managed in current cardiology practice. This is because of complexities in definition and assessment, as mentioned earlier, as well as because many symptoms of psychological distress are easily confused with physical disease, for example, fatigue, weight loss, poor appetite, or trouble sleeping.

No consensus has been reached on whether screening for and treatment of emotional problems, such as depression, anxiety, and PTSD, should be carried out systematically in cardiac patients because it is uncertain whether screening for and treating these problems translate into better quality of life or improved prognosis. Additionally, clinical trials of psychological or psychiatric interventions have thus far yielded only modest improvements in psychological well-being with null or uncertain effect on cardiac outcomes.⁵⁷ Despite this controversy, psychological interventions, such as individual or group counseling, stress management, support for self-care, and pharmacotherapy, are likely to add benefit for the control of standard risk factors, for promotion of a healthy lifestyle, and for management of psychological distress when added to standard cardiac rehabilitation or as part of a coordinated care management approach.^{58,59} Some evidence indicates that individualizing such interventions to address individual risk and sex-specific issues may prove beneficial.⁶⁰ Such programs require substantial resources and commitment from both patients and staff. However, their potential benefits in improving psy-

chological well-being should not be discounted.

Current clinical guidelines in the United States mention depression only as a psychosocial factor that is reasonable for the non-mental health clinician to recognize if patients have access to adequate care support systems (class of recommendation, IIa; level of evidence, B). These guidelines further state that treatment of depression may be reasonable for its clinical benefits other than improving CVD outcomes (class IIb; level of evidence, C).⁵¹ In contrast, European guidelines, although noting the limitations of screening for depression, recognize the importance of a comprehensive approach for detection of psychosocial risk factors by using at least a preliminary assessment with a short series of yes/no questions and recommend a multimodal behavioral intervention approach that integrates health education, physical activity, and psychological therapy (class Ia; level of evidence, A).³⁷ In the case of clinically significant symptoms of depression or other psychosocial factors, the European guidelines recommend consideration of interventions such as psychotherapy, medication, or collaborative care (class IIa; level of evidence, A).

Psychotherapy

Psychotherapy helps people with depression understand the types of behavior, emotions, and ideas that contribute to depression; regain a sense of control and pleasure in life; and learn coping skills.⁶¹ Psychodynamic therapy is based on the assumption that a person is depressed because of unresolved, generally unconscious conflicts, often stemming from childhood. Interpersonal therapy focuses on behavior and interactions with family and friends. The primary goal of this therapy is to improve communication skills and increase self-esteem during a short period. Cognitive-behavioral therapy (CBT) involves examining thought patterns that can be negative and self-defeating and going over the basis of such thoughts and how they contribute to emotions. Psychotherapy has been shown to be equally effective for depression as medications, and some people, especially those with early life stress issues, may not respond to medication without psychotherapy.

Because of the increased risk for mortality in cardiac patients with depression, it was assumed that successful treatment of depression would reduce this risk. The ENRICHD (Enhanced Recovery in Coronary Heart Disease Patients) trial, though, did not find such a beneficial effect of CBT on cardiac outcomes; however, the average improvement in depression in comparison to placebo was modest. In post hoc analyses, patients who responded to treatment did have a better outcome than those who did not respond.⁶²

Other types of therapy have also been shown to be useful for depression and anxiety and include interpersonal therapy, stress management, and stress reduction techniques such as deep breathing, progressive muscle relaxation, yoga, meditation, and mindfulness-based stress reduction.

Antidepressant Medications

Antidepressant medications are another proven method for the treatment of depression. Antidepressants act on the serotonin and norepinephrine systems in the brain, as well as on other neurotransmitter systems. Drugs that increase brain levels of serotonin and norepinephrine have both been shown to be effective treatments of depression and anxiety. Antidepressants typically bind to proteins called transporters that are responsible for taking the neurotransmitter back up into the neuron after it has been released into the synapse, thereby causing an increase in neurotransmitter at the synapse level. Many of the antidepressant drugs block the serotonin transporter, the norepinephrine transporter, or a combination of the two. The original drugs, the tricyclics, had a more general effect on blockage of neurotransmitter uptake.

Tricyclic Antidepressants

Tricyclics represent the first class of medications found to be efficacious for the treatment of depression. They include imipramine (Tofranil), doxepin (Sinequan), amoxapine (Asendin), and amitriptyline (Elavil). Tricyclics increase norepinephrine and serotonin levels in the synapse. The most common side effects of tricyclics are anticholinergic side effects, which include dry mouth, constipation, memory problems, confusion, blurred vision, sexual dysfunction, and decreased urination. Tricyclics have properties like quinidine: they lead to an increase in the PR interval, prolongation of the QRS duration and QT interval, and flattening of the T wave on the electrocardiogram. These effects are not usually of clinical significance. However, tricyclics should be avoided in patients with preexisting cardiac conduction defects, congestive heart failure, or recent myocardial infarction. Prolongation of the QT interval beyond 0.44 second is associated with an increased risk for malignant ventricular arrhythmias (torsades de pointes). Indeed, tricyclic medications have been correlated with an increased risk for malignant ventricular arrhythmias and sudden cardiac death (see Chapter 39). For patients who suffer a cardiac event while being treated with a tricyclic, abrupt withdrawal from the tricyclic medication can be associated with an increased risk for arrhythmias. Consequently, these medications should be tapered slowly over time. If prolongation of the QT interval or development of hypotension in patients treated with a tricyclic

becomes a problem, treatment with tricyclics should be slowly tapered off and a selective serotonin reuptake inhibitor (SSRI), venlafaxine, or bupropion initiated (see the next section). These latter medications are preferred in patients in whom new onset of depression develops after acute myocardial infarction.

The anticholinergic side effects of the tricyclics are especially troublesome for older adults because they are more susceptible to the memory impairment and orthostatic hypotension associated with these medications. For this reason it is recommended that tricyclics not be prescribed to older adults.

Selective Serotonin Reuptake Inhibitors

The SSRIs include fluoxetine (Prozac, Sarafem), paroxetine (Paxil), fluvoxamine (Luvox), citalopram (Celexa), escitalopram (Lexapro), and sertraline (Zoloft). They act by blocking the transporter that brings serotonin back from the synapse into the neuron and thus have a different side effect profile than the tricyclics do, specifically, fewer to no anticholinergic and cardiac effects, which make them the antidepressant medications of choice in the cardiac patient population.

SSRI medications have not been shown to have greater efficacy than the older tricyclics in the treatment of depression, although a larger number of patients drop out of treatment while taking tricyclics because of side effects. In general, SSRIs, like the older tricyclics, have only modest efficacy over placebo. About 80% of the improvement with antidepressants comes from the placebo response.⁶³ Patients with mild or moderate depression do not have clinically meaningful responses to antidepressants, whereas those with severe depression have more substantial responses.

The primary advantage of SSRIs in cardiac patients is a smaller risk for cardiovascular and anticholinergic side effects. Side effects of SSRIs include nausea, diarrhea, headache, insomnia, and agitation. One of the most troubling side effects of the SSRIs is sexual dysfunction, which includes loss of libido, delayed ejaculation, and erectile dysfunction. Antidepressants without sexual dysfunction-related side effects can be given instead of an SSRI in these cases, including Wellbutrin, Remeron, and Desyrel, all drugs not in the SSRI class.

SSRI treatment, especially fluoxetine, is associated with an increase in the risk for bleeding. For cardiac patients treated with aspirin or other antiplatelet/anticoagulation medications, bleeding can be an important issue. Stopping treatment with SSRIs suddenly can also result in a potent withdrawal syndrome, including agitation, nervousness, and sometimes suicidal thoughts. SSRIs can cause akathisia and other extrapyramidal side effects, like the antipsychotics. Akathisia includes feelings of restlessness, pacing, and internal stiffness, which subjectively are very uncomfortable. However, these symptoms are not common and are treatable with benzodiazepines or low doses of propranolol. A more troubling problem is the potential for suicidality associated with SSRIs. All antidepressant medications may be associated with an increased risk for suicide.

Short-term trials of SSRIs have found them to be safe and effective for cardiac patients. Although treatment of depression has not been demonstrated to improve cardiac outcomes, in a number of trials treatment responders appeared to have better cardiac outcomes than nonresponders did, thus suggesting that response to treatment may be a key factor.⁶² Several cohort studies, however, have shown increased cardiac risk with longer term use of SSRIs. For example, the Nurses' Health Study, which examined more than 60,000 women without a history of heart disease, found that those taking antidepressants were three times as likely to have sudden cardiac death than were women not taking antidepressants, even after adjusting for the severity of depression and risk factors for heart disease.⁶⁴ There was an equal risk with SSRIs as with other antidepressants outside the SSRI class. However, sudden cardiac death in healthy women is fairly rare, and in this study only 46 of 100,000 women taking an SSRI experienced sudden cardiac death. The WISE (Women's Ischemia Syndrome Evaluation) study compared women with and without antidepressant and anxiolytic therapy.⁶⁵ Antidepressant use was associated with a doubling of risk for cardiovascular events and death. Although anxiolytic use alone was not associated with increased

risk, women who were taking both antidepressants and anxiolytics had a fourfold or greater risk for cardiovascular events and mortality.

Norepinephrine Reuptake Inhibitors

Antidepressant medications designed to specifically block reuptake of norepinephrine into the synapse are called norepinephrine reuptake inhibitors (NRIs). Medications in the NRI group include desipramine (Norpramin) and nortriptyline (Aventyl, Pamelor). They have a more favorable profile in terms of anticholinergic side effects and effects on the heart and blood pressure than the tricyclics do.

Serotonin and Norepinephrine Dual Reuptake Inhibitors

The latest group of antidepressants has dual reuptake inhibition for serotonin and norepinephrine (SNRIs) and includes venlafaxine (Effexor) and duloxetine (Cymbalta). In general, SNRIs have shown better treatment response for depression than have SSRIs and tricyclics. When multiple studies were combined, with treatment response defined as at least a 50% reduction in symptoms of depression, venlafaxine had a success rate of 74%, which was significantly better than SSRIs, with a 61% success rate, and tricyclics, with a 58% success rate.

SNRIs, however, can cause a number of side effects. Both venlafaxine and duloxetine can cause dizziness, constipation, dry mouth, headache, changes in sleep, or more rarely, a serotonin syndrome consisting of restlessness, shivering, and sweating. Venlafaxine has been associated with a dose-dependent increase in blood pressure, which is of particular concern for cardiac patients, especially those with preexisting hypertension. Although not well studied, there is a good possibility that duloxetine has similar effects. Venlafaxine seems to carry the greatest risk for suicidality among all the antidepressants, with a threefold increased risk for attempted or completed suicide.

Monoamine Oxidase Inhibitors

Drugs that block the monoamine oxidase inhibitor (MAOI) enzyme and therefore boost the monoamines (serotonin, norepinephrine) include phenelzine (Nardil) and tranylcypromine (Parnate). They have a more favorable cardiovascular profile than the tricyclics, with little or no effect on cardiac conduction, although they can be associated with orthostatic hypotension and weight gain. They can cause a “wine and cheese reaction” of potentially life-threatening elevations in blood pressure if taken with foods that are high in tyramine content, including wine, cheese, chocolate, and beer. Medications that can precipitate hypertensive reactions if a patient is also taking an MAOI include those with sympathomimetic effects (e.g., amphetamines, ephedrine, cocaine). MAOIs should also not be taken together with meperidine (Demerol). Because of the risk for hypertensive crises, MAOIs are not recommended for use in cardiac patients, and indeed they are no longer commonly prescribed in general.

Antidepressants with Novel Mechanisms of Action

Some drugs act on various neurotransmitter systems or in general are poorly understood in terms of mechanism of action. Bupropion (Wellbutrin) acts primarily on dopamine systems and is used for both depression and smoking cessation under the brand name Zyban. Side effects include weight loss and restlessness, as well as possible increases in blood pressure; high doses can rarely cause seizures. Mirtazapine (Remeron) is a tetracyclic antidepressant that has actions on a number of different receptor systems. It blocks presynaptic noradrenergic α_2 receptors with associated enhancement of norepinephrine release. Mirtazapine also increases the release of serotonin. Side effects include sweating and shivering, tiredness, strange dreams, dyslipidemia, weight gain, anxiety, and agitation. It can be associated with mild orthostatic hypotension and anticholinergic side effects. Short-term randomized trials in cardiac patients have not shown an increase in mortality or cardiovascular events associated with these medications.

Other drugs with mixed actions include trazodone (Desyrel) and maprotiline (Ludiomil). The profile of these medications appears to be safe in terms of anticholinergic side effects and effects on the heart

and blood pressure. Desyrel can rarely cause priapism, however (extended painful erection that requires emergency treatment).

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) is used as a last resort for the treatment of depression in patients who have had multiple failed trials of psychotherapy and medication. ECT has an 80% response rate, which is a better response rate than seen with medications, and contrary to popular belief, it is a safe procedure. ECT causes profound hemodynamic changes, including bradycardia (up to frank asystole, which may last for a few seconds), followed by tachycardia and hypertension. These effects, however, are transient and typically resolve within 20 minutes. Possible complications include persistent hypertension, arrhythmias, asystole lasting longer than 5 seconds, ischemia, and heart failure. Older age and preexisting CVD, including hypertension, coronary artery disease, congestive heart failure, aortic stenosis, implanted cardiac devices, and atrial fibrillation, have been associated with increased complication rates. Nonetheless, most complications remain minor and transient, and the vast majority of patients can safely complete treatment.

There are no absolute contraindications to ECT. However, the procedure should be delayed in patients who are hemodynamically unstable or have new-onset or uncontrolled hypertension. In patients with stable coronary heart disease and controlled hypertension, medications can be continued through the morning of the procedure. In patients with an implanted pacemaker, the pacemaker should be tested before and after ECT; the magnet should be placed at the patient's bedside in the event that electrical interference leads to pacemaker inhibition and bradycardia. ECT appears to be safe in patients with an ICD. The detection mode of the ICD should be turned off during ECT, and continuous electrocardiographic monitoring should be performed, with resuscitative equipment available at the patient's bedside in the event that external defibrillation is necessary.

Anxiolytic Medications Benzodiazepines

In the 1960s, benzodiazepines displaced barbiturates as the most commonly used treatments of insomnia and were used commonly in patients with anxiety and depression. They were originally marketed as having less potential for dependence and abuse, although this did not bear out over time. Benzodiazepines act on a receptor in the brain called the gamma-aminobutyric acid (GABA)-benzodiazepine receptor complex. This is the same complex that alcohol and the inhibitory transmitter GABA bind to, although benzodiazepines have their own binding site. The benzodiazepines most commonly prescribed today include alprazolam (Xanax), which is used mainly for anxiety attacks and panic disorder; clonazepam (Klonopin), which is used for epilepsy; and temazepam (Restoril). Other benzodiazepine medications that are longer acting and still sometimes used for the treatment of insomnia include oxazepam (Serax), lorazepam (Ativan), chlordiazepoxide (Librium), clorazepate (Tranxene), and diazepam (Valium), among others. Differences in the individual benzodiazepines are related to the time of onset of action and duration of effect. On average, benzodiazepines increase the user's sleep time by about 1 hour per night.

The side effects from benzodiazepines during the day can cause serious problems, including daytime drowsiness, dizziness, light-headedness, memory problems, and increased motor vehicle accidents. Use of benzodiazepine medications is associated with a 60% increase in road traffic accidents. The risk is increased further with concurrent alcohol use and in older age. All medications for insomnia are not recommended for long-term use.

The primary concern in cardiac patients using benzodiazepines is a potential risk for respiratory suppression. For this reason, benzodiazepines with a shorter half-life should be preferred over those with longer half-lives in cardiac patients. In patients with cardiac disease and associated pulmonary impairment, these medications should be used with caution.

Nonbenzodiazepine “Z-Drug” Medications

The newer generation of insomnia medications, zaleplon (Sonata), zolpidem (Ambien), eszopiclone (Lunesta), and zopiclone (Imovane), or “Z” drugs, act on specific subsets of the GABA receptor. They are commonly called “nonbenzodiazepine” medications, but the name is misleading in that they bind to the same GABA-benzodiazepine receptor complex in the brain as benzodiazepines and alcohol do. The difference is that they bind to a different part of the same receptor complex. They have been marketed as having less dependency and fewer side effects than the older generation of benzodiazepine medications, and some argue that these drugs have less potential for abuse than the benzodiazepines. However, studies have not shown them to be more effective or safer than the benzodiazepines, and no difference between the different Z drugs in safety or efficacy has been established. As for benzodiazepines, general side effects for all these medications include memory impairment, drowsiness, and dizziness. An increased risk for road traffic accidents was also seen with zopiclone. Sonata has a much shorter half-life (1 hour) than do Ambien (2.5 hours) and Lunesta (6 hours) and is therefore promoted as being associated with less drowsiness the next day.

Medications with Other Mechanisms of Action

Rozerem (Ramelteon) is a melatonin receptor agonist that is used for insomnia. Side effects include headache, drowsiness, fatigue, nausea, dizziness, and more rarely, diarrhea and depression. Advantages of this medication are the absence of abuse potential and the lack of withdrawal symptoms.

Buspirone (BuSpar) is an agonist of the serotonin 1A receptor and relatively free of next-day drowsiness and memory impairment or the potential for dependence or abuse. Buspirone is efficacious in the treatment of anxiety and is preferable to the benzodiazepines for the treatment of cardiac patients because it lacks respiratory suppressive effects. Side effects are minimal and include nausea, headache, and light-headedness. It has no known adverse cardiac effects.

Alternative Medicines, Herbs, and Supplements

Some natural remedies have been recommended for depression and anxiety. However, in general, few large controlled studies have evaluated these approaches, and the quality of the research has been highly variable.

St. John’s Wort

St. John’s wort (*Hypericum perforatum*) is a popular medication for the over-the-counter treatment of mild depression; 12% of Americans report using it at least once a year. St. John’s wort has actions similar to antidepressants, including inhibition of monoamine oxidase, inhibition of reuptake of serotonin, and actions on sigma receptors. St. John’s wort had been shown to be better than placebo in some earlier studies and equally effective as tricyclic antidepressants for the treatment of depression. However, most of these earlier studies were poorly controlled and did not use standard definitions of depression. More recent studies have been highly variable in their results. A 2008 Cochrane review confirmed substantial heterogeneity of results across trials but nonetheless concluded that based on the evidence available, *Hypericum* extracts are 28% superior to placebo in patients with major depression, are as effective as standard antidepressants, and have fewer side effects than standard antidepressants do.⁶⁶ St. John’s wort can interact with a number of medications, including digoxin, theophylline, protease inhibitors, and cyclosporine.

Omega-3 Fatty Acids

Low dietary intake and low serum or red blood cell levels of omega-3 fatty acids are associated with depression in patients with and without coronary heart disease and with increased risk for cardiac mortality. Two omega-3 fatty acids, eicosapentaenoic acid and docosahexaenoic acid, are found in high concentration at neuronal synapses in the human brain and are essential for neuronal functioning. In depressed psychiatric patients who were otherwise medically

healthy, some studies have indicated that supplementation with omega-3 fatty acids dramatically improves the efficacy of antidepressants; however, few controlled studies have been conducted. A recent study in patients with stable coronary heart disease and depression, though, showed no improvement in depression after 10 weeks of treatment with omega-3 fatty acids plus sertraline versus placebo plus sertraline.⁶⁷

Other Remedies

Some natural remedies that are marketed to improve depression and cognition may do more harm than good and are not recommended in cardiac patients. One of these is kava (or kava kava), an extract of the roots of the Polynesian plant *Piper methysticum* that is used in the South Pacific for its sedative, aphrodisiac, and stimulatory effects. Active compounds include the kava pyrones. Some controlled trials have shown that kava reduces anxiety in patients with anxiety disorders. The side effects of kava, however, are not insignificant and include dizziness, dry mouth, gastric disturbance, diarrhea, drowsiness, depression, and more rarely, liver failure. Because of the risk for liver failure, kava is not recommended for the treatment of mood disorders.

Vitamins A and E have been promoted to improve cognition and mood. Both these vitamins, however, have been associated with increased risk for CVD in several large placebo-controlled trials. B vitamins and folate have also been advocated as a way to improve cognition and depression through their influence on levels of the amino acid homocysteine in the 1-carbon cycle metabolic pathway; however, data proving such effects are limited. A related natural compound that is marketed as a supplement for the treatment of depression is *S*-adenosylmethionine (SAME), which acts as a methyl group donor in methylation reactions. Some data suggest that SAME is better than placebo and equivalent to tricyclic antidepressants in efficacy with fewer side effects. However, there is considerable variability in results, and studies have also not had adequate follow-up to determine the long-term benefits of SAME for depression, although it does not appear that SAME has long-term toxicity.

Exercise

A number of studies dating from the mid-1990s to more recently have shown that various forms of exercise improve depression (see [Chapter 79](#)). A recent meta-analysis reported a large effect of exercise on depression, with an average difference in the Hamilton Rating Scale for Depression of 3.4, which denotes clinically significant improvement.⁶⁸ The results of other meta-analyses are similar, although the effects appear to be smaller when only the methodologically most rigorous trials are included.⁶⁹ In general, studies have found larger effect sizes in clinically depressed samples than in non-clinical samples.

It has also been shown that exercise for a half hour a day, 6 days per week is an effective exercise “dose” to improve the mood of people who have mild to moderate depression. Therefore, aerobic exercise at a dose consistent with public health recommendations for prevention of CVD is also an effective treatment of mild to moderate depression. In addition, exercise may complement the effects of antidepressant medication in depressed patients who do not have a complete response to medication.

Summary of Management Considerations

Even though treatment of depression or anxiety has not been shown to improve cardiovascular outcomes in cardiac patients, it is still necessary to recognize and manage these problems if they are severe or persistent to promote patient wellness and quality of life, as well as improve patients’ ability to adhere to treatments and lifestyle recommendations.

In many cases the cardiologist can address the problem without the need for immediate referral to a psychiatrist. Many patients complaining of “anxiety” may actually have worry about their cardiac condition. In this situation, education about the cardiac condition,

listening to patients' concerns, and allowing them to ventilate their worries may go a long way toward relieving distress. The next step is to determine whether patients are having thoughts of taking their own life or are having severe impairment in functioning that would necessitate referral to a psychiatrist, psychologist, or social worker, depending on the severity of the condition and the type of treatment (medications versus psychotherapy or counseling).

The cardiologist may also start a trial of medication. Benzodiazepines can be used short-term to manage anxiety but should be limited to less than 2 weeks to reduce the risk for development of dependence. They can be useful, however, in the period before antidepressants start working. An alternative for the treatment of anxiety that does not have any risk for dependence or respiratory suppression is buspirone. Antidepressants useful in cardiac patients include SSRIs (paroxetine, fluoxetine, sertraline, and others), mirtazapine, and bupropion. Patients who fail to respond to these medications may respond to venlafaxine or duloxetine, with careful monitoring of blood pressure. A healthy lifestyle, especially physical activity tailored to patients' functional capabilities, should always be recommended to decrease depression and improve well-being. Many self-help books are available that patients can buy to teach themselves stress reduction techniques, in addition to resources in the community such as counselors and social workers, who can teach these skills either individually or in classes.

Cardiologists are increasingly being asked to evaluate and treat patients with a primary neurologic disorder because of the potential for associated cardiac involvement. In several neurologic disorders, the cardiovascular manifestations are responsible for a greater proportion of morbidity and mortality risk than that attributable to the neurologic manifestations. This chapter reviews those neurologic disorders associated with important cardiovascular manifestations or sequelae.

THE MUSCULAR DYSTROPHIES

The muscular dystrophies are a group of inherited skeletal muscle diseases. Most also have direct effects on cardiac muscle, with manifestations including heart failure, conduction disease and heart block, atrial and ventricular arrhythmias, and sudden death. With improved multidisciplinary care, patients are living longer, with increased numbers exhibiting associated cardiac-related issues. As discussed next individually, the following muscular dystrophies can manifest with cardiovascular involvement:

- Duchenne and Becker muscular dystrophies
- Myotonic dystrophies
- Emery-Dreifuss muscular dystrophies and associated disorders
- Limb-girdle muscular dystrophies
- Facioscapulohumeral muscular dystrophy

Duchenne and Becker Muscular Dystrophies

Genetics. Both Duchenne and Becker muscular dystrophy are X-linked recessive disorders caused by mutations in the dystrophin gene (see Chapters 8 and 32). The dystrophin protein and dystrophin-associated glycoproteins provide a structural link between the myocyte cytoskeleton and extracellular matrix functioning to link contractile proteins to the cell membrane.¹ Dystrophin messenger RNA is expressed predominantly in skeletal, cardiac, and smooth muscle with lower levels in brain. Absence of dystrophin leads to membrane fragility resulting in myofibril necrosis and eventual loss of muscle fibers with fibrotic replacement. Abnormalities in dystrophin and in dystrophin-associated glycoproteins underlie the degeneration of cardiac and skeletal muscle in several inherited myopathies including X-linked dilated cardiomyopathy. Beyond the inherited disorders, the loss of dystrophin plays a role in myocyte failure in other cardiomyopathies including sporadic idiopathic, viral myocarditis, and those associated with coronary artery disease. In Duchenne muscular dystrophy, dystrophin is nearly absent whereas in Becker muscular dystrophy, dystrophin is present but reduced in size or amount. This leads to the characteristic rapidly progressive skeletal muscle disease in Duchenne and the more benign course in Becker muscular dystrophy. Cardiac involvement is seen in both disorders, and the severity is not correlated with the severity of skeletal muscle involvement. Mutations in specific domains of the large dystrophin gene are associated with a higher risk for cardiomyopathy.²

Clinical Presentation

Duchenne muscular dystrophy is the most common inherited neuromuscular disease with an incidence of 1 case in 3600 to 6000 live male births.³ Patients typically present with skeletal muscle weakness before the age of 5 years, which progresses if untreated such that boys become wheelchair-bound by their early teens (Fig. 87-1). Historically, death occurs by age 25 years, primarily from respiratory dysfunction and less often from heart failure. A multidisciplinary treatment approach including steroids, scoliosis surgery, ventilatory support, and cardiac therapy has improved survival. Becker muscular dystrophy is less common than Duchenne muscular dystrophy, is associated with a more variable presentation of skeletal muscle weakness (see Fig. 87-1), and carries a better prognosis, with most patients surviving to the age of 40 to 50 years.

In both Duchenne and Becker muscular dystrophy, elevated serum creatine kinase activity is observed, at levels more than 10 and 5 times normal values, respectively.

Cardiovascular Manifestations

Most patients with Duchenne muscular dystrophy develop a cardiomyopathy, but symptoms can be masked by severe skeletal muscle weakness. Preclinical cardiac involvement is present in one fourth by age 6, with the onset of clinically apparent cardiomyopathy after age 10 common. Up to 90% of patients with Duchenne muscular dystrophy 18 years of age or older develop a dilated cardiomyopathy. Predilection for involvement in the inferobasal and lateral left ventricle has been observed (Fig. 87-2). As with the skeletal muscle weakness, cardiac involvement in Becker muscular dystrophy is more variable than in Duchenne muscular dystrophy, ranging from none or subclinical to severe cardiomyopathy requiring transplant. Cardiac involvement in Becker muscular dystrophy is independent of the severity of skeletal muscle involvement, with some but not all investigators observing increased likelihood of cardiovascular disease in older patients. More than one half of patients with subclinical or benign skeletal muscle disease were noted to have cardiac involvement if carefully evaluated. Progression in the severity of cardiac involvement is common. Cardiomyopathy can initially solely involve the right ventricle.

Thoracic deformities and a high diaphragm can alter the cardiovascular examination in patients with Duchenne muscular dystrophy. A reduction in the anterior-posterior chest dimension is commonly responsible for a systolic impulse displaced to the left sternal border, a grade 1 to 3/6 short midsystolic murmur in the second left interspace and a loud pulmonary component of the second heart sound. In both Duchenne and Becker types of muscular dystrophy, mitral regurgitation is observed. The presence of mitral regurgitation is related to posterior papillary muscle dysfunction in Duchenne muscular dystrophy and to mitral annular dilation in Becker muscular dystrophy.

(In **C**, specimen was stained for dystrophin antibody.) (From Rapezzi C, Leone O, Biagini E, et al: Echocardiographic clues to diagnosis of dystrophin-related dilated cardiomyopathy. *Heart* 93:10, 2007.)

Female carriers of Duchenne and Becker muscular dystrophy are at increased risk for dilated cardiomyopathy.

Electrocardiography

In a majority of patients with Duchenne muscular dystrophy, the electrocardiographic tracing is abnormal (see Chapter 12). The classically described electrocardiographic pattern shows distinctive tall R waves and increased R/S amplitude in V_1 and deep narrow Q waves in the left precordial leads possibly related to the posterolateral left ventricular involvement (Fig. 87-3). Other common findings include short PR interval and right ventricular hypertrophy. No association between the presence of a dilated cardiomyopathy and electrocardiographic abnormalities has been established.⁴ In Becker muscular dystrophy, electrocardiographic abnormalities are present in up to 75% of the patients. The electrocardiographic abnormalities observed include tall R waves and increased R/S amplitude in V_1 , akin to that seen in Duchenne muscular dystrophy. Incomplete right bundle branch block also is a frequent finding that may be related to early involvement of the right ventricle. In patients with dilated cardiomyopathy, a left bundle branch block is common.

Echocardiography and Other Imaging Modalities

Clinical care guidelines recommend screening echocardiography at diagnosis or by the age 6 of years and subsequently every 2 years until the age of 10 and annually thereafter in boys with Duchenne muscular dystrophy³ (this and other cardiac imaging modalities are described more fully in Chapters 14 to 18). Abnormalities in strain imaging, diastolic dysfunction, and regional wall motion abnormalities can precede global systolic dysfunction in both Duchenne and Becker muscular dystrophy.⁵ Regional abnormalities in the posterobasal and lateral wall typically occur earlier than in other areas (see Fig. 87-2). A process akin to left ventricular noncompaction can be observed, possibly resulting from compensatory mechanisms in response to the failing dystrophic myocardium. Mitral regurgitation can result from dystrophic changes in the posterior leaflet papillary muscles. Cardiac magnetic resonance imaging is more sensitive in detecting subclinical ventricular involvement and fibrosis.

Arrhythmias

In Duchenne muscular dystrophy, persistent or labile sinus tachycardia is the most common arrhythmia recognized (see Chapter 37).

A

B

FIGURE 87-3 Dilated cardiomyopathy in a 19-year-old man with Duchenne muscular dystrophy. **A**, ECG showing a QRS complex that is typical of Duchenne dystrophy, with tall R waves in lead V_1 and deep narrow Q waves in leads I and aVL. **B**, Two-dimensional echocardiogram (parasternal four-chamber view) showing a dilated, thinned left ventricle (LV).

Atrial arrhythmias including atrial fibrillation and atrial flutter occur in the setting of respiratory dysfunction and cor pulmonale or are associated with a dilated cardiomyopathy. Abnormalities in atrioventricular conduction have been observed, with both short and prolonged PR intervals recognized. Ventricular arrhythmias occur on monitoring in 30%, primarily ventricular premature beats. Complex ventricular arrhythmias have been reported, more commonly in patients with severe skeletal muscle disease. Sudden death occurs in Duchenne muscular dystrophy, typically in patients with end-stage muscular disease. Whether the sudden death is caused by arrhythmias is unclear. Several follow-up studies have shown a correlation between sudden death and the presence of complex ventricular arrhythmias. The presence of ventricular arrhythmias was not a predictor for all-cause mortality.

Arrhythmia manifestations in Becker muscular dystrophy typically relate to the severity of the associated structural cardiomyopathy. Distal conduction system disease with complete heart block and bundle branch reentry ventricular tachycardia has been observed.

Treatment and Prognosis

Duchenne muscular dystrophy is a progressive skeletal and cardiac muscle disorder. Steroids and steroid derivatives are effective in delaying skeletal muscle disease progression and also appear to decrease the progression to a dilated cardiomyopathy. Drisapersen is an antisense oligonucleotide that facilitates “exon skipping” of a nonsense mutation in the dystrophin gene, which creates a premature stop signal in the translation of the dystrophin mRNA, thereby leading to a prematurely truncated, dysfunctional dystrophin protein. Nonsense mutations of dystrophin genes are responsible for dystrophinopathy in approximately 10% to 15% of boys with the disease. Oligonucleotide-mediated exon skipping restores the open reading frame of the dystrophin gene, resulting in an internally deleted (truncated) but semi-functional dystrophin. Early phase clinical trials have demonstrated clinical benefit with an acceptable safety profile, and the FDA has given drisapersen favorable guidance for a regulatory path forward, under an accelerated approval pathway. Gene replacement therapy also holds future promise. A primary cardiac cause of death is recognized to play an increasingly significant role because of delayed mortality with improved respiratory support. There is an equal distribution of cardiac death from heart failure and sudden death. Angiotensin-converting enzyme inhibitors and beta blockers can improve left ventricular function in patients treated early.^{1,2} Spironolactone may provide additional benefit (see Chapters 24 and 25).⁶ Other advanced therapies such as implantable cardioverter-defibrillators are of uncertain role but should be considered individually based on patient status and wishes (see Chapter 36). Whether heart failure therapies improve long-term outcomes is unclear. Age at death has increased so that the majority of patients survive into their 30s.

In patients with Becker muscular dystrophy, an improvement in left ventricular function also is observed after treatment with angiotensin-converting enzyme (ACE) inhibitors and beta blockers.¹ Screening left ventricular imaging is recommended as in Duchenne muscular dystrophy. Advanced heart failure therapy, including primary prevention implantable cardioverter-defibrillators, is appropriate in patients with cardiomyopathy. Patients with Becker muscular dystrophy with advanced heart failure can undergo cardiac transplantation, with expected outcomes similar to those for non-muscular dystrophy cohorts of age-matched patients with dilated cardiomyopathy.⁷ Female carriers of Duchenne and Becker muscular dystrophies do not develop a cardiomyopathy during childhood, and screening can be delayed until later in adolescence. Whether carriers benefit from afterload reduction therapy is unknown, but such treatment would seem reasonable based on shared mechanisms. Once heart failure is established, conventional therapy is indicated. Cardiac transplantation also has been reported in carriers.

Myotonic Dystrophies

Genetics. The myotonic dystrophies are autosomal dominant disorders characterized by myotonia, which is a delayed muscle relaxation after contraction, weakness and atrophy of skeletal muscles, and

systemic manifestations including endocrine abnormalities, cataracts, cognitive impairment, and cardiac involvement (Fig. 87-4). Two distinct mutations are responsible for the myotonic dystrophies. In myotonic dystrophy type 1, the mutation is an amplified trinucleotide cytosine-thymine-guanine (CTG) repeat found on chromosome 19. Whereas unaffected patients have 5 to 37 copies of the repeat, patients with myotonic dystrophy have 50 to several thousand repeats. A direct correlation exists between an increasing number of CTG repeats and earlier age at onset and increasing severity of neuromuscular involvement. Cardiac involvement including conduction disease and arrhythmias also correlate with the length of repeat expansion (Fig. 87-5). It is typical for the CTG repeat to expand as it is passed from parents to offspring, resulting in the characteristic worsening clinical manifestations in subsequent generations, termed anticipation.

Myotonic dystrophy type 2, also called proximal myotonic myopathy, has generally less severe skeletal muscle and cardiac involvement than in type 1. Both congenital presentation and cognitive impairment are lacking in myotonic dystrophy type 2—typically the most severely involved subsets of the type 1 patients. The genetic mutation responsible for myotonic dystrophy type 2 is a tetranucleotide repeat expansion, cytosine-cytosine-thymine-guanine (CCTG), found on chromosome 3. Intergenerational contraction of the repeat expansion has been reported, and there is no apparent relationship between the degree of expansion and clinical severity.

The molecular mechanism by which both myotonic dystrophies exert their similar phenotypic presentations is by the toxic effects of the large mutant RNA expansion on nuclear RNA binding proteins.⁸ A recent study suggests that cardiac pathology in both myotonic dystrophy type 1 and 2 is related to gap junction (GJA1) and calcium channel (CACNA1C) protein overexpression⁹ (Fig. 87-6).

Clinical Presentation

The myotonic dystrophies are the most common inherited neuromuscular disorders in patients presenting as adults. Until recently, studies have not genetically differentiated myotonic dystrophy types 1 and 2, so the clinical characteristics described probably are for a mixed group of such disorders. Type 1 is significantly more common than type 2, except possibly in certain areas of northern Europe. The global incidence of myotonic dystrophy type 1 has been estimated to be 1 in 8000, although it is higher in certain populations, such as

FIGURE 87-4 The patient was a 54-year-old man with myotonic dystrophy type 1. Typical characteristics of balding, thin face, and distal muscle atrophy are evident.

FIGURE 87-5 Relationship between the PR interval on the ECG and age and CTG repeat sequence expansion in 342 patients with myotonic dystrophy type 1. There is a direct relationship between age and CTG repeat sequence expansion and the severity of cardiac conduction disease, as quantified by the PR interval. The relationship suggests that cardiac involvement in myotonic dystrophy type 1 is a time-dependent degenerative process, with the rate of progression modulated by the extent of CTG repeat expansion. (From Groh WJ, Lowe MR, Zipes DP: Severity of cardiac conduction involvement and arrhythmias in myotonic dystrophy type 1 correlates with age and CTG repeat length. *J Cardiovasc Electrophysiol* 13:444, 2002.)

FIGURE 87-7 Grip myotonia in myotonic dystrophy. The patient is unable to fully open the hand (A) after exerting a grip (B).

Subcapsular cataracts are commonly observed. In general, cardiac symptoms appear after the onset of skeletal muscle weakness but can be the initial manifestation of the disease.

Myotonic dystrophy type 2 also manifests with myotonia, muscle weakness, cataracts, and endocrine abnormalities, as in type 1. Age at symptom onset typically is older in myotonic dystrophy type 2.

Cardiovascular Manifestations

Cardiac pathology in the myotonic dystrophies involves degeneration, fibrosis, and fatty infiltration preferentially targeting the specialized conduction tissue including the sinus node, atrioventricular node, and His-Purkinje system (Fig. 87-8). Degenerative changes are observed in working atrial and ventricular tissue but only rarely progress to a symptomatic dilated cardiomyopathy. It is not clear if there are differences in the cardiac pathology observed between myotonic dystrophy type 1 and 2. Patients with type 2 typically demonstrate cardiac involvement later in life or not at all. The primary cardiac manifestations of the myotonic dystrophies are arrhythmias.

Electrocardiography

A majority of adult patients with myotonic dystrophy type 1 exhibit electrocardiographic abnormalities. In a large, unselected middle-aged U.S. myotonic population, abnormal electrocardiographic patterns were seen in 65% of the patients.¹⁰ Abnormalities included first-degree atrioventricular block in 42%, right bundle branch block in 3%, left bundle branch block in 4%, and nonspecific intraventricular conduction delay in 12%. Q waves not associated with a known myocardial infarction are common. Electrocardiographic abnormalities are less common in younger patients. Conduction disease worsens with advancing age (Fig. 87-9).

Electrocardiographic abnormalities are less common in myotonic dystrophy type 2, occurring in approximately 20% of middle-aged patients.

Echocardiography and Other Imaging Modalities

Left ventricular systolic and diastolic dysfunction, left ventricular hypertrophy, mitral valve prolapse, regional wall motion abnormalities, and left atrial dilatation have been reported in patients with myotonic dystrophy type 1 at moderate prevalence rates.¹¹ Clinical heart failure is observed but is less common than are arrhythmias. Left ventricular hypertrophy and ventricular dilatation have been reported in myotonic dystrophy type 2. Cardiac magnetic resonance imaging may be more sensitive than echocardiography for detection of early cardiac involvement.

FIGURE 87-6 Model of microRNA-1 (miR-1) alteration in myotonic dystrophies. **A**, Muscleblind-like protein 1 (MBNL1) and protein lin-28 homolog A (LIN28) compete for binding to pre-miR-1 loop. In presence of MBNL1, the processing of pre-miR-1 in mature miR-1 is favored and results in regulated expression of miR-1 targets. **B**, In people with myotonic dystrophy, the sequestration of MBNL1 by expanded CUG (type 1) or CCUG (type 2) repeats allows LIN28 or LIN28B to bind to pre-miR-1, which promotes its consequent uridylation by terminal uridylyltransferase-4 (TUT4). Uridylated pre-miR-1 is resistant to Dicer cleavage, which results in lower amounts of miR-1 and increased levels of its targets, alpha-1 connexin 43 (GJA1) and alpha-1C subunit L-type calcium channel (CACNA1C). CTL = control; DM = myotonic dystrophy; IGF = insulin-like growth factor; IGFR1 = insulin-like growth factor receptor 1; MEF2A = myocyte enhancer factor 2A. (From Rau F, Freyermuth F, Fugier C, et al: Misregulation of miR-1 processing is associated with heart defects in myotonic dystrophy. *Nature Struct Mol Biol* 18:840, 2011.)

French Canadians, and lower to nonexistent in other populations, such as African blacks. The age at onset of symptoms and diagnosis averages 20 to 25 years. A congenital presentation is seen in severely affected patients with myotonic dystrophy type 1. Common early manifestations are related to weakness in the muscles of the face, neck, and distal extremities. On examination, myotonia can be demonstrated in the grip, thenar muscle group, and tongue (Fig. 87-7). Diagnosis when the patient is asymptomatic is possible using electromyography and genetic testing. Muscle weakness is progressive.

FIGURE 87-8 Histopathologic features of the atrioventricular bundle in myotonic dystrophy. **A**, Fatty infiltration in a specimen from a 57-year-old man. **B**, Focal replacement fibrosis and atrophy in a specimen from a 48-year-old woman. Arrows demarcate expected size and shape of the branching atrioventricular bundle. (**A**, Masson trichrome stain, $\times 90$; **B**, hematoxylin-eosin stain, $\times 90$.) LBB = left bundle branch; RBB = right bundle branch. (From Nguyen HH, Wolfe JT III, Holmes DR Jr, Edwards WD: Pathology of the cardiac conduction system in myotonic dystrophy: A study of 12 cases. *J Am Coll Cardiol* 11:662, 1988.)

Arrhythmias

Patients with myotonic dystrophy type 1 demonstrate a wide range of arrhythmias. At cardiac electrophysiologic study, the most common abnormality found is a prolonged His-ventricular (H-V) interval. Conduction system disease can progress to symptomatic atrioventricular block and necessitate pacemaker implantation. The prevalence of permanent cardiac pacing in patients with myotonic dystrophy type 1 varies widely between studies based on referral patterns and the indications used for implant. Updated practice guidelines have recognized that asymptomatic conduction abnormalities in neuromuscular diseases such as myotonic dystrophy may warrant special consideration for pacing.¹²

Atrial arrhythmias, primarily atrial fibrillation and atrial flutter (see Chapter 38), are the most common arrhythmias observed.¹⁰ Ventricular tachycardia can occur. Patients with myotonic dystrophy type 1 are at risk for ventricular tachycardia occurring as a consequence of reentry in the diseased distal conduction system, as characterized by bundle branch reentry and interfascicular reentry tachycardia (Fig. 87-10). Therapy with right bundle branch or fascicular radiofrequency ablation can be curative.

Up to one third of deaths in myotonic dystrophy type 1 are sudden; presumably, most are due to arrhythmias.¹⁰ The entity of sudden death is second only to respiratory failure as a cause of death. The mechanisms leading to sudden death are not clear. Distal conduction disease producing atrioventricular block can result in the lack of an appropriate escape rhythm and asystole or bradycardia-mediated ventricular fibrillation. Sudden death can occur in myotonic dystrophy type 1 despite pacing, implicating ventricular arrhythmias. Non-arrhythmia causes of sudden death, probably acute respiratory issues, play some role.

Arrhythmias and sudden death have been reported in myotonic dystrophy type 2 but seem to be rarer than in type 1.

Treatment and Prognosis

Neurologists recognize the risk for cardiac issues in the myotonic dystrophies and will refer to cardiology. Cardiac manifestations occur in both myotonic dystrophy types 1 and 2 and therefore diagnostic evaluation and therapy should be done in both. Cardiac disease is observed at a younger age in myotonic dystrophy type 1 compared with type 2. Echocardiography or other imaging modalities can determine if structural abnormalities are present. Cardiac imaging in adults should be done at diagnosis or with new symptoms. If no significant abnormalities are observed repeat evaluation every 3 to 5 years is appropriate. In the patient with a dilated cardiomyopathy, standard therapy including ACE inhibitors and beta blockers has improved symptoms. There are no data on the role of ACE inhibitors or beta blockers to prevent development of a cardiomyopathy in myotonic dystrophy. Patients presenting with symptoms indicative of arrhythmias such as syncope and palpitations should undergo an evaluation, often including a cardiac electrophysiologic study, to determine an underlying causative disorder. Annual electrocardiograms (ECGs) are recommended in asymptomatic patients. The role and interval for ambulatory ECG (Holter) monitoring are not clear (see Chapter 34). Significant or progressive electrocardiographic abnormalities despite a lack of symptoms is an indication for consideration for prophylactic pacing.¹² The presence of severe electrocardiographic conduction abnormalities and atrial arrhythmias were independent risk factors for sudden death.¹⁰ The strategy of pacing when the H-V interval is greater than or equal to 70 milliseconds at cardiac electrophysiologic study decreased sudden death in a large observational trial.¹³ Implantable cardioverter-defibrillators may be more appropriate prophylactic therapy than pacemakers.¹⁴ Certain families may be more prone to arrhythmia manifestations of myotonic dystrophy. Anesthesia in patients with myotonic dystrophy increases both the risk of respiratory failure and arrhythmias. Careful monitoring during the perioperative period is mandatory. Monitored anesthesia during cardiac device implants should be done under an anesthesiologist's care.

In patients presenting with wide complex tachycardia, cardiac electrophysiologic study with particular evaluation for bundle branch reentry tachycardia should be done. Implantable cardioverter-defibrillators are being increasingly used in patients with myotonic dystrophies.

The course of neuromuscular abnormalities in the myotonic dystrophies is variable. Respiratory failure from progressive muscle dysfunction is the most common cause of death. Some patients, however, are only minimally limited by weakness up to the age of 60 to 70 years. Sudden death can reduce survival in patients with the myotonic dystrophies including those minimally symptomatic from a neuromuscular status. Decisions regarding prophylactic cardiac devices need to be made with full consideration of all aspects for the care of the myotonic patient.

Emery-Dreifuss Muscular Dystrophy and Associated Disorders

Genetics and Cardiac Pathology. Emery-Dreifuss muscular dystrophy is a rare inherited disorder in which skeletal muscle symptoms are often mild but with cardiac involvement that is both common and serious. The disease is classically inherited in an X-linked recessive fashion but there is heterogeneity with families that fit an X-linked dominant, autosomal dominant and autosomal recessive inheritance pattern. The gene responsible for the X-linked Emery-Dreifuss muscular dystrophy, *STA*, encodes a nuclear membrane protein termed emerin. Mutations in genes found on chromosome 1 encoding two other nuclear membrane proteins, lamins A and C, have been identified as being responsible for a variety of other disorders with a phenotypic expression similar to X-linked Emery-Dreifuss muscular dystrophy. The disorders include autosomal dominant and recessive Emery-Dreifuss muscular dystrophy, autosomal dominant dilated cardiomyopathy with conduction disease, autosomal dominant

FIGURE 87-9 ECGs obtained 1 year apart in a 36-year-old man with myotonic dystrophy (the *top tracings* are older). Note the abnormal Q waves in the precordial leads. An increasing PR interval and QRS duration are observed, consistent with increasing severity of conduction disease.

limb-girdle muscular dystrophy with conduction disease, and lipodystrophy with associated cardiac abnormalities.¹⁵

Nuclear membrane proteins such as emerin and lamins A and C provide structural support for the nucleus and interact with the cell's cytoskeletal proteins. Mutations in the tail regions of lamins A and C are responsible for the majority of cases of autosomal dominant Emery-Dreifuss muscular dystrophy with a phenotype of both cardiac and skeletal muscle involvement. Mutations in the rod domain of the lamin A/C gene primarily cause isolated cardiac disease including dilated cardiomyopathy, conduction system degeneration, and atrial and ventricular arrhythmias.

Clinical Presentation

Emery-Dreifuss muscular dystrophy is characterized by a triad of early contractures of the elbow, Achilles tendon, and posterior cervical muscles; slowly progressing muscle weakness and atrophy, primarily in humeroperoneal muscles; and cardiac involvement (**Fig. 87-11**). The disorder has been labeled “benign X-linked muscular dystrophy” to differentiate the slowly progressive muscular weakness from that of Duchenne muscular dystrophy. In the autosomal dominant and recessive inheritance of Emery-Dreifuss muscular dystrophy, a more variable phenotypic expression and penetrance typically are observed. A mutation in the lamin A/C gene also is responsible for an autosomal dominantly-inherited familial partial lipodystrophy characterized by marked loss of subcutaneous fat, diabetes, hypertriglyceridemia, and cardiac abnormalities.

Cardiovascular Manifestations

Arrhythmias and dilated cardiomyopathy are the major manifestation of cardiac disease in Emery-Dreifuss muscular dystrophy and its associated disorders. In X-linked recessive Emery-Dreifuss muscular dystrophy abnormalities in impulse generation and conduction are common. ECGs are abnormal by age 20 to 30 years, commonly

showing first-degree atrioventricular block. The atria appear to be involved earlier than the ventricles, with atrial fibrillation and atrial flutter, or more classically, permanent atrial standstill and junctional bradycardia. Abnormalities in impulse generation or conduction are present in virtually all patients by age 35 to 40 years, and requirement for pacing is typical. Ventricular arrhythmias including sustained ventricular tachycardia and ventricular fibrillation occur. Sudden, presumably cardiac, death before age 50 is observed. Prophylactic implantable cardioverter-defibrillators are used.¹⁶ Female carriers of X-linked recessive Emery-Dreifuss muscular dystrophy do not exhibit skeletal muscle disease but acquire late cardiac disease including conduction abnormalities, and sudden death can occur. Although arrhythmias are the most common presentation of cardiac involvement in X-linked recessive Emery-Dreifuss muscular dystrophy, a dilated cardiomyopathy can rarely develop. The dilated cardiomyopathy is more common in patients in whom survival has been improved with cardiac device implantation. Both autopsy and endomyocardial biopsy specimens have shown cardiac fibrosis.

Patients with disorders caused by lamin A and C mutations typically present at 20 to 40 years of age with cardiac conduction disease, atrial fibrillation, and dilated cardiomyopathy. Skeletal muscle disease typically is subclinical or absent. Progression of a cardiomyopathy to the extent that heart transplantation is required has been described. Sudden death in those patients with a dilated cardiomyopathy occurs. Pacing often is required for symptomatic heart block. Implantable cardioverter-defibrillators are the appropriate cardiac device for a majority of patients.¹⁶

Treatment and Prognosis

Patients should be monitored for development of electrocardiographic conduction abnormalities and arrhythmias. Annual evaluation is appropriate. Atrioventricular block can occur with anesthesia.

FIGURE 87-10 Bundle branch reentry tachycardia in a 34-year-old woman with myotonic dystrophy type 1 presenting with a symptomatic (recurrent syncope) wide-complex tachycardia. **A**, ECG showing sinus rhythm and a QRS complex with left bundle branch block. **B**, ECG showing a rapid monomorphic tachycardia easily inducible on electrophysiologic study, with left bundle morphology.

Continued

FIGURE 87-10, cont'd C, Recordings during electrophysiologic study, including the surface ECG (leads I, II, III, V₁) and intracardiac ECGs. A monomorphic ventricular tachycardia is induced with atrial-ventricular (A-V) dissociation and His association, consistent with bundle branch reentry tachycardia. H = His recording; HRA = high right atrium; HV = RV; RV = right ventricle; a14 = HRA; a15-24 = His proximal; a25-34 = His distal.

Sudden death even in patients with pacemakers has been observed. Prophylactic placement of an implantable cardioverter-defibrillator is advocated in patients with Emery-Dreifuss muscular dystrophy and its associated disorders if significant electrocardiographic conduction disease is present and pacing is being considered.^{15,16} Whether implantable cardioverter-defibrillators should be considered only in a certain subgroups of patients or in all patients with significant conduction disease or cardiomyopathy is not clear. In a large observational European series, risk factors for sudden death and appropriate implantable cardioverter-defibrillator therapy included nonsustained ventricular tachycardia, left ventricular ejection fraction less than 45% at presentation, male sex, and lamin A or C non-missense mutations.¹⁶ Routine imaging for evaluation of left ventricular function is appropriate in all patients with Emery-Dreifuss muscular dystrophy and the associated disorders. Patients with left ventricular dysfunction should benefit from pharmacologic therapy but data on this issue are limited. Successful heart transplantation has been reported. Female carriers of X-linked recessive Emery-Dreifuss muscular dystrophy develop conduction disease, and electrocardiographic monitoring on a routine basis is appropriate.

Limb-Girdle Muscular Dystrophies

Genetics. The limb-girdle muscular dystrophies are a group of disorders with a limb-shoulder and pelvic girdle distribution of weakness, but with otherwise heterogeneous inheritance and genetic cause.¹⁷ Autosomal recessive (subtypes 2A to 2P), dominant (subtypes 1A to 1H), and sporadic patterns of inheritance have been observed. Genes involved include those encoding dystrophin-associated glycoproteins, sarcomeric proteins, sarcolemma proteins, nuclear membrane proteins, and cellular enzymes. An autosomal dominant limb-girdle muscular dystrophy (subtype 1B) with a high prevalence of arrhythmias and a late dilated cardiomyopathy is caused by mutations encoding lamin A/C, as in Emery-Dreifuss muscular dystrophy.

An autosomal recessive or sporadic limb-girdle muscular dystrophy associated with a progressive dilated cardiomyopathy is caused by mutations affecting the function of the dystrophin-glycoprotein complex, including sarcoglycan and fukutin-related proteins (subtypes 2C to 2F and 2I, respectively). The sarcoglycans complex with dystrophin-associated glycoproteins to counteract mechanical stress associated with contraction. Fukutin-related proteins affect glycosylation of a dystrophin-associated glycoprotein. An autosomal recessive limb-girdle muscular dystrophy associated with a variable onset of a dilated cardiomyopathy is caused by a mutation in a sarcolemmal repair protein termed dysferlin (subtype 2B). Other subtypes of limb-girdle muscular dystrophy are not commonly associated with cardiac or arrhythmia abnormalities.

Clinical Presentation

The onset of muscle weakness is variable but usually occurs before age 30. The recessive disorders tend to cause earlier and more severe weakness than the dominant disorders. Creatine kinase levels are moderately elevated. Patients commonly present with complaints of difficulty with walking or running secondary to pelvic girdle involvement. As the disease progresses, involvement of the shoulder muscles and then more distal muscles occurs, with sparing of facial involvement. Slow progression to disability and death can occur.

Cardiovascular Manifestations

As with many of the features of the limb-girdle muscular dystrophies, heterogeneity in the presence and degree of cardiac involvement is usual.

The limb-girdle muscular dystrophies types 2C to 2F, termed *sarco-glyconopathies*, manifest with a dilated cardiomyopathy.¹⁸ Cardiac abnormalities are detected in a majority of patients, with a smaller proportion symptomatic. Cardiomyopathy is most common in the subtype 2E and least common in the subtype 2D. ECGs show similar abnormalities as in Duchenne and Becker muscular dystrophy

FIGURE 87-11 Emery-Dreifuss muscular dystrophy in a 28-year-old man presenting with syncope. **A**, Contractures of the elbow and atrophy in the humeroperoneal muscles. **B**, ECG obtained at initial presentation showed atrial fibrillation with slow ventricular rate and a QRS complex with left bundle branch block. (Courtesy Dr. Robert M. Pascuzzi.)

including an increased R wave in V_1 and lateral Q waves. Imaging can show a progressive dilated cardiomyopathy. A severe cardiomyopathy, including presentation with heart failure in childhood, can occur. Sudden death associated with the cardiomyopathy has been reported. Limb-girdle muscular dystrophy type 2I, caused by mutations in fukutin-related proteins, is associated with a dilated cardiomyopathy. The mutation is also responsible for a form of congenital muscular dystrophy. The age at disease onset and severity of skeletal muscle involvement are variable, with symptoms emerging in some patients during childhood but more typically developing after the age of 20 years. Approximately one half of patients with limb-girdle muscular dystrophy type 2I exhibit cardiac involvement (**Fig. 87-12**). Cardiac involvement has been reported as more common in males. Cardiac findings include regional wall motion abnormalities or a dilated cardiomyopathy and heart failure. Advanced heart failure can occur. Conduction disease does not occur separate from the

structural cardiac involvement. Limb-girdle muscular dystrophy type 2B, termed a dysferlinopathy, has been associated with increased myocardial fibrosis on cardiac magnetic resonance imaging and variably with a dilated cardiomyopathy.

The autosomal dominant limb-girdle muscular dystrophy type 1B is caused by mutations in the gene encoding lamins A and C with a clinical phenotype similar to Emery-Dreifuss muscular dystrophy. Skeletal muscle involvement is mild, with cardiac involvement both common and severe. Atrioventricular block develops by early middle age, often necessitating pacing. Sudden death is observed even in patients with pacemakers. A progressive dilated cardiomyopathy can occur, typically after the development of conduction disease.

Treatment and Prognosis

Because of the heterogeneous nature of limb-girdle muscular dystrophy, specific recommendations for routine cardiac evaluation and

FIGURE 87-12 Cardiac involvement in a 33-year-old man with limb-girdle muscular dystrophy type 2I demonstrated by magnetic resonance imaging: Four-chamber views in diastole (**A**) and systole (**B**); midventricular short-axis views in diastole (**C**) and systole (**D**). The images demonstrate enlarged left and right ventricles, with moderately impaired left ventricular function (calculated ejection fraction = 39%). LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle. (From Gaul C, Deschauer M, Tempelmann C, et al: Cardiac involvement in limb-girdle muscular dystrophy 2I: Conventional cardiac diagnostic and cardiovascular magnetic resonance. *J Neurol* 253:1317, 2006.)

therapy are based upon the disease type. In patients and families with limb-girdle types that manifest with cardiac involvement, evaluation for ventricular dysfunction, conduction disease, and arrhythmias is indicated. Patients with dilated cardiomyopathies respond to standard heart failure therapy. Heart transplantation has been reported. Prophylactic placement of an implantable cardioverter-defibrillator instead of a pacemaker has been recommended in patients with lamin A and C mutation after conduction disease is observed. In a large observational European series, risk factors for sudden death and appropriate implantable cardioverter-defibrillator therapy included nonsustained ventricular tachycardia, left ventricular ejection fraction less than 45% at presentation, male sex, and lamin A or C non-missense mutations.¹⁶

Facioscapulohumeral Muscular Dystrophy

Genetics. Facioscapulohumeral muscular dystrophy is the third most common muscular dystrophy after the Duchenne and myotonic types. It is a disorder of autosomal dominant inheritance in which the primary genetic mutation occurs at chromosomal locus 4q35, with a contraction of a D4Z4 repeat sequence. The repeat sequence is required to suppress transcription of adjacent genes and its contraction results in inappropriate protein expression. Genetic heterogeneity with a second mutation has been reported.

Clinical Presentation

Muscle weakness tends to follow a slowly progressive but variable course. The patient initially presents with facial and/or shoulder girdle muscle weakness, which progresses to involve the pelvic musculature.

Cardiovascular Manifestations

Cardiac involvement in facioscapulohumeral muscular dystrophy is reported but does not constitute as significant of a problem in

prevalence or severity as in other muscular dystrophies. In some series, no evidence of cardiac abnormalities were found. Other series have reported a propensity toward arrhythmias primarily of atrial origin, with atrioventricular conduction abnormalities less common.¹⁹

Treatment and Prognosis

Because significant clinical cardiac involvement is rare in facioscapulohumeral muscular dystrophy, specific monitoring or treatment recommendations are not well defined. Yearly ECGs have been recommended.

FRIEDREICH ATAXIA

Genetics. Friedreich ataxia is a spinocerebellar degenerative disease of autosomal recessive inheritance, characterized clinically by ataxia of the limbs and trunk, dysarthria, loss of deep tendon reflexes, sensory abnormalities, skeletal deformities, diabetes mellitus, and cardiac involvement.²⁰ The primary genetic abnormality is an expansion of a trinucleotide repeat, guanine-adenine-adenine (GAA), in an intron of a gene that encodes a 210-amino acid mitochondrial protein called frataxin. Loss of frataxin affects mitochondrial iron homeostasis, making the cell susceptible to oxidative stress (**Fig. 87-13**). Messenger RNA for frataxin is highly expressed in the heart. Endomyocardial biopsy samples have shown deficient function in mitochondrial respiratory complex subunits and in aconitase, an iron-sulfur protein involved in iron homeostasis. Histopathologic examination has revealed myocyte hypertrophy and degeneration, interstitial fibrosis, active muscle necrosis, bizarre pleomorphic nuclei, and periodic acid-Schiff-positive deposition in both large and small coronary arteries. Degeneration and fibrosis in cardiac nerves and ganglia and the conduction system also have been observed. Deposition of calcium salts and iron has been reported.

An earlier age at symptom onset, increasing severity of neurologic symptoms, and worsening left ventricular hypertrophy are observed in patients in whom genetic testing shows a greater expansion of the GAA repeat.

In a majority of patients with Friedreich ataxia, neurologic dysfunction is progressive. Cardiac death occurs in those with a dilated cardiomyopathy. Heart failure is the most common cause of death.²¹

FIGURE 87-15 ECG from a 34-year-old man with Friedreich ataxia. Widespread ST and T changes are evident. (Courtesy Dr. Charles Fisch, Indiana University School of Medicine, Indianapolis.)

FIGURE 87-16 **A**, Gross and histologic specimens from a 17-year-old boy with Friedreich ataxia whose ECG progressed from a normal appearance at age 13 years to a minimally dilated, hypocontractile left ventricle (LV) 3 to 4 years later. The gross specimen (left) shows a mildly dilated LV with normal wall thickness; the walls were flabby. The microscopic section from the left ventricular free wall (right) shows marked connective tissue replacement. Although specifically sought, small-vessel coronary artery disease was not identified. **B**, Two-dimensional echocardiogram (apical window) showing the mildly dilated, thin-walled LV. Ao = aorta; LA = left atrium. (**A**, **B**, From Child JS, Perloff JK, Bach PM, et al: Cardiac involvement in Friedreich ataxia. *J Am Coll Cardiol* 7:1370, 1986.)

Arrhythmias complicate heart failure deaths in one third of patients. Respiratory dysfunction is the second most common cause of death. Death from heart failure occurs earlier than respiratory death, typically before the age of 30 years. The role of pharmacologic or defibrillator therapy in Friedreich ataxia and dilated cardiomyopathy has not been evaluated, but such conventional therapy should be strongly considered until a disease-modifying treatment is available.²³

LESS COMMON NEUROMUSCULAR DISEASES ASSOCIATED WITH CARDIAC MANIFESTATIONS

The Periodic Paralyse

Genetics and Clinical Presentation. The primary periodic paralyses are rare, nondystrophic disorders of autosomal dominant inheritance resulting from abnormalities in ion channel genes.²⁴ They can be classified into hypokalemic and hyperkalemic periodic paralyses

and Andersen-Tawil (long-QT 7) syndrome (see Chapter 33). In addition, acquired hypokalemic periodic paralysis may complicate thyrotoxicosis, especially in men of Asian descent. All patients present with episodic attacks of flaccid paralysis precipitated by variable environmental stimuli including cold and exercise, or with rest after exercise. A late-onset fixed myopathy can occur in hypokalemic and hyperkalemic periodic paralyses.

Hypokalemic periodic paralysis is characterized by episodic attacks of weakness exacerbated by carbohydrate load or occurring during rest after exercise and is associated with decreased serum potassium levels at onset. Penetrance is nearly complete in male patients and 50% in female patients. It is caused by point mutations in the α -1 subunit of the dihydropyridine-sensitive calcium channel (CACNA1S) or in the α subunit of the skeletal muscle sodium channel (SCN4A). Approximately 20% of cases are of uncertain genetic cause. One third of the cases of thyrotoxic hypokalemic periodic paralysis are caused by mutations in an inward rectifier potassium channel, Kir2.6, which is regulated by thyroid hormone.

Hyperkalemic periodic paralysis also manifests with episodic weakness but with symptoms worsening with potassium supplementation

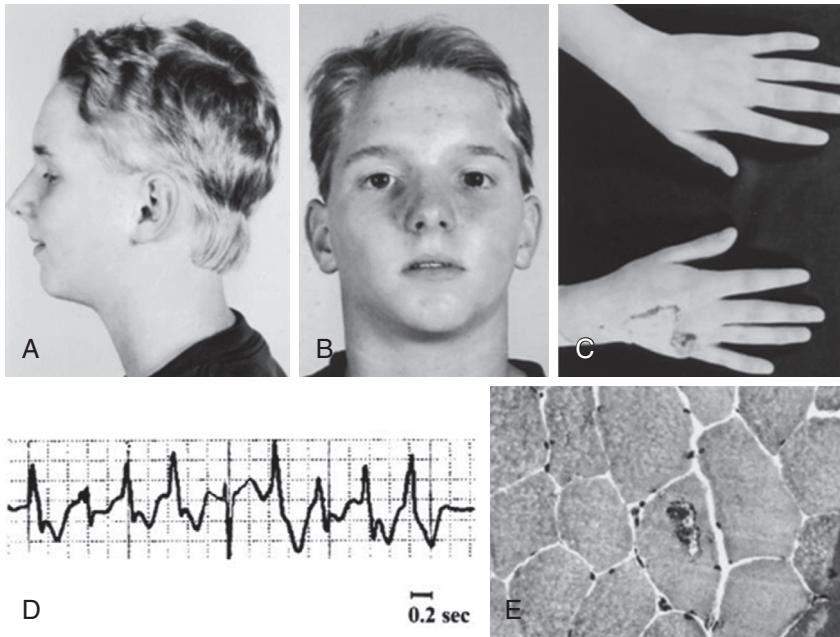

FIGURE 87-17 Andersen-Tawil syndrome. **A, B,** An affected patient exhibits characteristic low-set ears, hypertelorism, micrognathia, and clinodactyly of the fifth digits (**C**). **D,** ECG rhythm strip demonstrating short runs of polymorphic ventricular tachycardia. **E,** Skeletal muscle biopsy specimen exhibiting tubular aggregates commonly observed in patients with periodic paralysis. (From Plaster NM, Tawil R, Tristani-Firouzi M, et al: Mutations in *Kir2.1* cause the developmental and episodic electrical phenotypes of Andersen's syndrome. *Cell* 105:511, 2001.)

and decreasing with carbohydrate load. Complete penetrance is observed. Potassium levels usually are high but may be normal during an attack. Hyperkalemic periodic paralysis is due primarily to mutations in the alpha subunit of *SCN4A*. Multiple different mutations in this gene have been reported that result in a potassium-sensitive failure of inactivation (gain of function) in the sodium channel. Hyperkalemic periodic paralysis is genetically heterogeneous; an *SCN4A* mutation is found in a majority of affected persons, but other loci also have been identified.

Andersen-Tawil syndrome is a distinct periodic paralysis associated with dysmorphic physical features of short stature, low-set ears, micrognathia, hypertelorism, and clinodactyly; abnormalities on the ECG include an abnormal QT-U wave pattern and ventricular arrhythmias²⁵ (Fig. 87-17). Weakness can be triggered by low, normal, or high potassium levels. Phenotypic variability and incomplete penetrance can complicate the diagnosis for a given family. Mutations in the *KCNJ2* gene encoding the inward rectifier potassium protein, Kir2.1 are responsible for 60% of cases. The genetic cause in the other 40% of patients is unknown. Andersen-Tawil syndrome has been given a long QT syndrome 7 nomenclature.

Cardiovascular Manifestations

The periodic paralyses are associated with ventricular arrhythmias. Most arrhythmias occur in hyperkalemic periodic paralysis and Andersen-Tawil syndrome. Bidirectional ventricular tachycardia has been observed without digitalis intoxication (see Chapters 12 and 33). The episodes of bidirectional ventricular tachycardia are independent of attacks of muscle weakness, do not correlate with serum potassium levels, and can convert to sinus rhythm with exercise. The tachycardia typically is less than 150 beats/min and well tolerated. Ventricular ectopy is common.

A prolonged QT interval can be observed. It can be episodic prolonging associated with weakness or hypokalemia, or occurring as a consequence of antiarrhythmia therapy, or may be constant. Andersen-Tawil syndrome is associated with a modest prolongation in the QT interval but more specifically a prolonged and prominent U wave. Ventricular arrhythmias including premature ventricular contractions, ventricular bigeminy, and nonsustained polymorphic ventricular tachycardia, primarily bidirectional tachycardia, is observed in Andersen-Tawil syndrome. Cardiac conduction abnormalities,

atypical of long QT syndromes, have been observed in Andersen-Tawil syndrome. Torsades de pointes is observed in Andersen-Tawil syndrome but is less common than in the other long QT syndromes. Syncope, cardiac arrest, and sudden death have been reported in the periodic paralyses, most prominently in the Andersen-Tawil syndrome. The factors that portend an increased risk of life-threatening arrhythmias are not clear.

Treatment and Prognosis

The episodes of weakness typically respond to measures that normalize potassium levels. Weakness in hyperkalemic periodic paralysis can respond to mexiletine. Weakness in hypokalemic periodic paralysis can respond to acetazolamide. Treatment of electrolytes usually does not ameliorate arrhythmias or, if it does, affords only transient improvement. Improvement in symptomatic nonsustained ventricular tachycardia associated with a prolonged QT interval has been reported with beta blocker therapy. Class 1A antiarrhythmia agents can worsen muscle weakness and exacerbate arrhythmias associated with a prolonged QT interval. Bidirectional ventricular tachycardia, not associated with a prolonged QT interval, may not respond to beta blocker therapy. Amiodarone, flecainide, and pacing have been observed to decrease episodes of ventricular tachycardia in Andersen-Tawil syndrome. The use of implantable cardioverter-defibrillators has been reported primarily in the Andersen-Tawil syndrome.

Mitochondrial Disorders

Genetics and Clinical Presentation. The mitochondrial disorders, also termed mitochondrial myopathies, encephalomyopathies, or respiratory chain disorders, are a heterogeneous group of diseases resulting from abnormalities in mitochondrial DNA and respiratory chain function.²⁶ The list of recognizable, distinct disorders is extensive. Mitochondrial DNA is inherited maternally, and some of these disorders are thus transmitted from mother to children of both sexes. Many other disorders involve abnormalities in nuclear DNA involved in mitochondrial form and function and are inherited in autosomal or X-linked fashion. Sporadic cases can occur. Disease severity can vary among family members because both mutant and normal mitochondrial DNA can be present in tissue in variable proportions—a phenomenon termed *heteroplasmy*. It is not surprising, in view of the metabolic function of mitochondria, that these disorders manifest with systemic pathology. Tissue with a high respiratory workload such as brain and skeletal muscle, especially extraocular, retina, and cardiac muscle, are primarily affected.

Mitochondrial disorders that have cardiac manifestations manifest as several clinical phenotypes. *Chronic progressive external ophthalmoplegia* is characterized by involvement of the extraocular muscles and can also involve oropharyngeal muscles. It is primarily a sporadic disease. *Kearns-Sayre syndrome*, a subtype of chronic progressive external ophthalmoplegia, is characterized by ocular myopathy, pigmentary retinopathy, and age at onset before 20 years. Diabetes, deafness, and ataxia can also be associated. *Myoclonus epilepsy with red ragged fibers* (MERRF) is characterized by myoclonus, seizures, ataxia, dementia and skeletal muscle weakness. *Mitochondrial myopathy with encephalopathy, lactic acidosis, and stroke-like episodes* (MELAS) is the most common of the maternally inherited mitochondrial disorders and is characterized by encephalopathy, subacute stroke-like events, migraine-like headaches, recurrent emesis, extremity weakness, and short stature. *Leber's hereditary optic neuropathy* causes subacute blindness, primarily in young men. Other mitochondrial point mutation disorders including *NARP* (neuropathy, ataxia and retinitis pigmentosa) and *Leigh syndrome* (subacute necrotizing encephalomyelopathy) cause neurodegenerative disorders primarily in children. *Barth syndrome* is an X-linked mitochondrial disease manifested by hypotonia, growth retardation, cyclic neutropenia, and 3-methylglutaconic aciduria in children. It is caused by mutations in exons of the nuclear gene encoding the tafazzin protein.

Cardiovascular Manifestations

In chronic progressive external ophthalmoplegia, most commonly in the Kearns-Sayre syndrome, cardiac involvement manifests primarily as conduction abnormalities. In the Kearns-Sayre syndrome, atrioventricular block is observed, usually manifesting after eye involvement. The H-V interval is prolonged, consistent with distal conduction disease. Permanent pacing often is required by the age of 20 years. An increased prevalence of electrocardiographic pre-excitation has also been reported. A dilated cardiomyopathy may occur.

In MERF and MELAS, a hypertrophic (symmetric or asymmetric) or dilated cardiomyopathy can occur.²⁷ An increased prevalence of electrocardiographic preexcitation also has been reported. Other disorders caused by mitochondrial point mutations can manifest with a similar cardiac phenotype of hypertrophic or dilated cardiomyopathy, often in children. Patients can present with chest pain with electrocardiographic abnormalities and myocardial perfusion defects. Whether the dilated cardiomyopathy represents a progression from the hypertrophic cardiomyopathy or a separate syndrome is not clear. The dilated cardiomyopathy can result in heart failure and death. MELAS also is associated with an increased risk of preexcitation and Wolff-Parkinson-White syndrome.²⁸ Leber's hereditary optic neuropathy can be associated with a hypertrophic cardiomyopathy and a short PR interval or preexcitation syndromes. Barth syndrome is associated with left ventricular noncompaction and endocardial fibroelastosis or a hypertrophic or dilated cardiomyopathy.²⁹ Heart failure and ventricular arrhythmias occur, often in young children. Cardiac transplantation has been reported.

Treatment and Prognosis

In Kearns-Sayre syndrome, the implantation of a pacemaker has been advocated when significant or progressive conduction disease is evident, even for those cases in asymptomatic patients. The degree of conduction disease that warrants prophylactic pacing is not clear. Implantable cardioverter-defibrillators are recommended in patients with both conduction disease and a dilated cardiomyopathy. In the other mitochondrial disorders, an understanding of the potential and specific presentations for cardiac involvement is necessary. Cardiac evaluation, electrocardiography, and echocardiography are recommended. The role of prophylactic or symptomatic heart failure pharmacotherapy has not been studied.

Spinal Muscular Atrophy

Genetics and Clinical Presentation. Spinal muscular atrophy is a lower motor neuron disorder manifesting as progressive, symmetric proximal muscular weakness.³⁰ It is the leading inherited cause of infant death. Spinal muscular atrophy is classified clinically by the age at symptom onset and disease severity into type I (Werdnig-Hoffman disease), type II (intermediate form), type III (Kugelberg-Welander disease), and type IV (adult-onset).

Spinal muscular atrophy is inherited in autosomal recessive fashion or is sporadic. Mutations or deletions in the telomeric *SMN* (survival of motor neuron) gene occur in most patients. The loss of functional *SMN* protein results in premature neuronal cell death. The *SMN* protein has a role in cardiac development.³¹

Cardiovascular Manifestations

Cardiac abnormalities associated with spinal muscular atrophy include complex congenital heart disease, cardiomyopathy, and arrhythmias. Congenital heart disease can be seen with types I and III spinal muscular atrophy. The most common abnormality is atrial septal defect with other reports observing ventricular septal defects and hypoplastic left heart. In spinal muscular atrophy type III, a dilated cardiomyopathy can occur, with endomyocardial biopsy demonstrating fibrosis. Progression to end-stage heart failure can occur. Arrhythmias reported include atrial standstill, atrial fibrillation, atrial flutter, and atrioventricular block. Permanent pacing for atrial standstill and atrioventricular block has been reported.

Treatment and Prognosis

In spinal muscular atrophy type I, severe skeletal muscle involvement with respiratory failure can limit lifespan, and treatment of associated cardiac abnormalities is often not done. In spinal muscular atrophy type III, awareness of the potential for associated cardiac abnormalities is necessary. Permanent pacing may be required. Directed therapy to improve functional *SMN* protein holds future promise.

Desmin-Related Myopathies

Genetics and Clinical Presentation. Desmin myopathy is a rare inherited dystrophic disorder affecting skeletal and cardiac muscle.³² The disorder is inherited primarily in autosomal dominant fashion, but autosomal recessive inheritance and sporadic disease have been reported. Typically, symptomatic skeletal muscle abnormalities will be recognized before cardiac involvement. Variability in the phenotype is recognized, however, and in members of affected families, a cardiomyopathy can develop without demonstrable skeletal muscle abnormalities. In a series of 425 dilated cardiomyopathy patients without skeletal muscle disease, desmin mutations were found in 6 (1.4%).³³ Desmin is a cytoskeletal protein that functions as the chief intermediate filament providing support to contracting skeletal and cardiac muscle. Mutations in the desmin gene lead to a disruption in forming functioning intermediate filaments.³⁴

Patients typically present in their late 20s with distal weakness that progresses proximally. Difficulty with ambulation and in severe cases, with respiration, can occur. Creatine kinase is mildly elevated in some patients. Muscle biopsy is diagnostic, showing desmin and other myofibrillar protein aggregation with immunostaining. Genetic testing is available.

Cardiovascular Manifestations

The cardiomyopathy associated with the desmin-related myopathies can occur prior to or after the diagnosis of a skeletal myopathy. The cardiac involvement observed typically consists of conduction system dysfunction before the onset of a dilated or restrictive cardiomyopathy. An arrhythmogenic right ventricular cardiomyopathy-like phenotype has been reported.³⁵ Syncope with need for pacemaker implantation has been described. Both sudden and heart failure-related deaths can occur. Sudden death can occur despite pacemaker implantation.

Treatment and Prognosis

The desmin-related myopathies should be considered in the differential diagnosis in individual patients or families presenting a skeletal or cardiac myopathy. Monitoring for the development of cardiac conduction and structural disease is indicated in affected families. Prophylactic pacemakers or implantable cardioverter-defibrillators should be considered in those patients with significant conduction disease, as in other neuromuscular disorders. Heart failure therapy in appropriate patients is indicated.

Guillain-Barré Syndrome

Clinical Presentation. The Guillain-Barré syndrome is an acute inflammatory demyelinating neuropathy characterized by peripheral, cranial, and autonomic nerve dysfunction (see Chapter 89).³⁶ It is the most common acquired demyelinating neuropathy. Men are more commonly affected than women. In two thirds of affected patients, an acute viral or bacterial illness, typically respiratory or gastrointestinal, precedes the onset of neurologic symptoms by within 6 weeks. The disorder typically manifests with pain, paresthesias, and symmetric limb weakness that progresses proximally and can involve cranial and respiratory muscles. One fourth of affected patients require assisted ventilation.

Cardiovascular Manifestations

Nonambulant patients are at increased risk for deep vein thrombosis and pulmonary emboli. Cardiac involvement related to accompanying autonomic nervous system dysfunction and is seen in one half of the patients. Cardiac manifestations include hypertension, orthostatic hypotension, resting sinus tachycardia, loss of heart rate variability, electrocardiographic ST abnormalities, and both bradycardia

and tachycardias. Microneurographic recordings have shown increased sympathetic outflow during the acute illness, which normalizes with recovery.

Life-threatening arrhythmias occur in Guillain-Barré syndrome, primarily in patients requiring assisted ventilation. Arrhythmias observed include asystole, symptomatic bradycardia, rapid atrial fibrillation and ventricular tachycardia or fibrillation. Death may occur as a consequence of an arrhythmia. Asystole commonly was associated with tracheal suctioning.

Treatment and Prognosis

Supportive care should include deep vein thrombosis prophylaxis in nonambulant patients. Early plasmapheresis or intravenous immunoglobulin can improve recovery. In severely affected patients, especially those requiring assisted ventilation, cardiac rhythm monitoring is mandatory. If serious bradycardia or asystole is observed, temporary or permanent pacing can improve survival. Atropine or isoproterenol during tracheal suctioning can be of benefit. The mortality rate in patients hospitalized with Guillain-Barré syndrome is as high as 15%. In patients who recover from Guillain-Barré syndrome, autonomic function also normalizes, and long-term arrhythmia risk has not been observed.

Myasthenia Gravis

Clinical Presentation

Myasthenia gravis is a disorder of neuromuscular transmission resulting from production of antibody targeted to the nicotinic acetylcholine receptor. The primary symptom, fluctuating weakness, usually begins with the eye and facial muscles and later can involve the large muscles of the limbs. Patients can present at any age, typically at a younger age in women and at an older age in men. Myasthenia gravis commonly is associated with hyperplasia or a benign or malignant tumor (thymoma) of the thymus gland.

Cardiovascular Manifestations

A myocarditis can occur in patients with myasthenia gravis, especially in those with a thymoma (see Chapters 67 and 81). The etiologic mechanism in myocarditis is a humoral immune response against striational proteins including titin, the ryanodine receptor, and a potassium-channel protein.^{37,38} Up to 16% of patients with myasthenia gravis have cardiac manifestations not explained by another etiologic disorder. Presentation with arrhythmia symptoms, which may include atrial fibrillation, atrioventricular block, asystole, ventricular tachycardia, sudden death, or heart failure, is typical. Autopsy findings are consistent with myocarditis, including giant cell myocarditis.³⁹

Treatment and Prognosis

Myasthenia gravis is treated with anticholinesterase and immunosuppressive agents. Thymectomy is often indicated. Anticholinesterase agents may slow the sinus rate, cause heart block and hypotension. Pacing can be necessary. Whether immunosuppressive agents or thymectomy improve associated cardiac disease is unknown. Case reports have described the development of rapidly progressive and fatal heart failure within weeks after thymoma resection in patients in whom with histologic examination showed giant cell myocarditis.

EPILEPSY

Cardiovascular Manifestations

Epilepsy is a complex brain disorder characterized by chronic seizures. Patients with epilepsy are at increased risk for sudden death of unknown cause that has been termed sudden unexpected death in epilepsy (SUDEP) (see Chapter 39).^{40,41} It is the leading cause of premature death in patients with epilepsy, with an incidence ranging

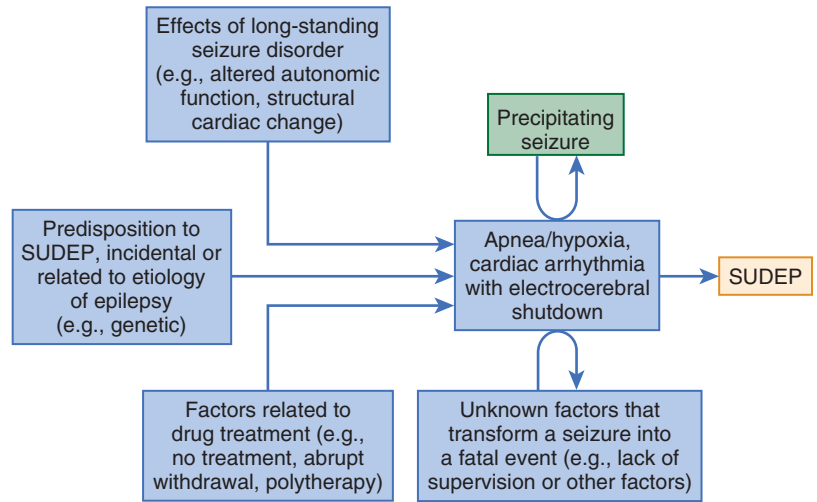

FIGURE 87-18 Interaction between proposed risk factors and triggers for SUDEP. (From Tomson T, Nashef L, Ryvlin P. Sudden unexpected death in epilepsy: Current knowledge and future directions. *Lancet Neurol* 7:1021, 2008.)

from 0.1 to 9.3 per 1000 patient-years, depending on the population studied. Adults with longstanding epilepsy are at the highest risk. The mechanisms leading to sudden death in epilepsy are not clear and probably vary. Central or obstructive apnea, mechanical suffocation, excessive respiratory secretions, acute pulmonary edema, and arrhythmias all may be involved (Fig. 87-18). A majority of witnessed sudden deaths occur at or in proximity to the time of a seizure. Severe bradycardia with sinus arrest has been documented in monitored patients during seizures including studies with an insertable loop recorder. Peri-ictal bradycardia is more common in patients with temporal lobe seizures. Whether bradycardia has a role in epileptic patients who experience sudden death is not clear. Primary ventricular arrhythmia disorders such as long-QT syndrome or right ventricular dysplasia can manifest with symptoms suggestive of epilepsy and could be responsible for a small proportion of sudden deaths.

Observational studies have assessed risk factors for SUDEP. These include male sex, onset of epilepsy at a young age, a long duration of epilepsy, high seizure frequency especially of generalized tonic-clonic seizures, and the need for polytherapy to control seizures.

Treatment and Prognosis

A primary arrhythmia disorder needs to be considered in the differential diagnosis of epilepsy. Patients with poorly controlled epilepsy should be aggressively evaluated and treated at tertiary epilepsy centers. Epilepsy surgery should be strongly considered. Patients with ictal bradycardia can require pacemaker implantation. Nighttime supervision of the epileptic patient may decrease the risk of sudden unexpected death.

ACUTE CEREBROVASCULAR DISEASE

Cardiovascular Manifestations

Acute cerebrovascular diseases, including subarachnoid hemorrhage, other stroke syndromes, and head injury, can be associated with severe cardiac manifestations (see Chapter 59).⁴² The mechanism by which cardiac abnormalities occur with brain injury is related to autonomic nervous system dysfunction, with both increased sympathetic and parasympathetic output. Excessive myocardial catecholamine release is primarily responsible for the observed cardiac pathology. Hypothalamic stimulation can reproduce the electrocardiographic changes observed in acute cerebrovascular disease. Electrocardiographic changes associated with hypothalamic stimulation or blood in the subarachnoid space can be diminished with spinal cord transection, stellate ganglion blockade, vagolytics, and adrenegic blockers.

FIGURE 87-19 ECG from a patient with cerebral hemorrhage. Deep and symmetric T wave inversions are evident. (Courtesy Dr. Charles Fisch, Indiana University School of Medicine, Indianapolis.)

Electrocardiographic abnormalities are observed in approximately 70% of patients with subarachnoid hemorrhage. Abnormalities including ST elevation and depression, T wave inversion, and pathologic Q waves are observed. Peaked inverted T waves and a prolonged QT interval can occur in a significant proportion of patients with electrocardiographic abnormalities (Fig. 87-19). Hypokalemia can be seen in patients with subarachnoid hemorrhage and can increase the likelihood of QT interval prolongation. Other stroke syndromes often are associated with abnormalities on the ECG, but whether these are related to the stroke syndrome or to underlying intrinsic cardiac disease often is difficult to discern. A prolonged QT interval is more common in subarachnoid hemorrhage than in other stroke syndromes. Closed head trauma can cause electrocardiographic abnormalities similar to those in subarachnoid hemorrhage, including a prolonged QT interval.

Myocardial damage with liberation of enzymes and subendocardial hemorrhage or fibrosis at autopsy can occur in the setting of acute cerebral disease.^{42,43} The term *neurogenic stunned myocardium* is used to describe the reversible syndrome. The process can manifest with selective apical involvement, a takotsubo cardiomyopathy. Cardiac troponin elevation and echocardiographic evidence of left ventricular dysfunction are present in a significant proportion of patients with subarachnoid hemorrhage. Patients with poorer neurologic status at admission are more likely to have an increased peak troponin level. Women are at higher risk for myocardial necrosis.

Pulmonary edema may accompany the acute neurologic insult. The edema can have both a cardiogenic component, related to systemic hypertension and left ventricular dysfunction, and a neurogenic (pulmonary capillary leak) component.

Life-threatening arrhythmias can occur in the setting of acute cerebrovascular disease. Ventricular tachycardia or fibrillation has been observed in patients with subarachnoid hemorrhage and head trauma. Torsades de pointes–type ventricular tachycardia can occur (Fig. 87-20). Often this is observed in the setting of a prolonged QT interval and hypokalemia. Stroke syndromes other than subarachnoid hemorrhage appear to be only rarely associated with serious

ventricular tachycardias. Atrial arrhythmias including atrial fibrillation and regular supraventricular tachycardia have been observed. Atrial fibrillation is most common in patients presenting with acute thromboembolic stroke. Separating an effect from the cause can be difficult. Bradycardias including sinoatrial block, sinus arrest, and atrioventricular block occur in up to 10% of patients with subarachnoid hemorrhage.

Treatment and Prognosis

Beta blockers appear to be effective in decreasing myocardial damage and in controlling both supraventricular and ventricular arrhythmias associated with subarachnoid hemorrhage and head trauma. Beta blockers increase the likelihood of bradycardia and cannot be used in patients with hypotension requiring vasopressors. Life-threatening arrhythmias occur primarily in the first day after a neurologic event. Continuous electrocardiographic monitoring during this period is indicated. Careful monitoring of potassium levels, especially in patients with subarachnoid hemorrhage, is warranted. Refractory ventricular arrhythmias have been controlled effectively with stellate ganglion blockade. Electrocardiographic abnormalities reflect unfavorable intracranial factors but do not appear to portend a poor cardiovascular outcome. The magnitude of peak troponin elevation is predictive for adverse patient outcomes including severe disability at hospital discharge and death.⁴² Other than contributing to the mortality secondary to acute arrhythmias, the myocardial necrosis does not appear to play a major factor affecting outcome.

Head injury (blunt trauma or gunshot wound) and cerebrovascular accidents are the leading causes of brain death in patients being considered as heart donors. These donors can manifest electrocardiographic abnormalities, hemodynamic instability, and myocardial dysfunction related primarily to adrenergic storm and not to intrinsic cardiac disease. Experimental studies on whether contractile performance recovers with transplantation are still controversial. Optimization of volume status and inotropic support with careful echocardiographic evaluation and possibly left-heart catheterization can allow the use of some donor hearts that would have otherwise been rejected.

FIGURE 87-20 Cardiac manifestations with cerebral hemorrhage in a 49-year-old patient. **A**, ECG recorded within 3 hours of admission and 4 hours after onset of symptoms. QT interval prolongation is evident. **B**, Electrocardiographic monitoring 6 hours after admission. Ventricular bigeminy precedes the onset of polymorphic ventricular tachycardia. Cardioversion was required. The patient subsequently was treated with a beta-adrenergic blocker without further ventricular tachycardia. **C**, On an ECG obtained 2 weeks after hospital admission, the QT interval has normalized.

The importance of multidisciplinary care that includes advanced cardiac therapy in patients with neurologic diseases with cardiac manifestations is increasingly being recognized. Adult cardiologists and electrophysiologists all participate in the management of patients. Referral to tertiary specialist is appropriate for the most complex patients. Controversies regarding appropriate use of pharmacotherapy and device therapy to manage cardiac manifestations in the neurologic diseases will be addressed further in clinical series and nonrandomized trials. The surety of therapeutic benefit afforded by assessment in a randomized controlled trial will not be available for a majority of these rare diseases. Gene-based or molecular-targeted therapy is under current evaluation in many of the neurologic diseases and holds future promise.

THE CARDIORENAL INTERSECTION

The heart and kidney functions interrelate inextricably. The kidneys receive 20% to 25% of the cardiac output, perfusing approximately 1 million nephrons (Fig. 88-1). This flow per unit weight exceeds by several-fold that of most other organs. The kidney has a central role in electrolyte balance, protein production and catabolism, and blood pressure regulation. Communication between the heart and the kidneys occurs at multiple levels, including the sympathetic nervous system (SNS), the renin-angiotensin-aldosterone system (RAAS), antidiuretic hormone, endothelin, and the natriuretic peptides. Elucidation of these pathways has led to development of some of the key diagnostic and therapeutic targets in contemporary cardiovascular medicine.

The obesity pandemic contributes to type 2 diabetes mellitus and hypertension, conditions that predispose to chronic kidney disease (CKD) and cardiovascular disease (CVD).¹ Of persons with diabetes for 25 years or longer, approximately 50% will develop diabetic nephropathy.² Approximately half of all cases of end-stage renal disease (ESRD) result from diabetic nephropathy. The aging of the population can be expected to accentuate this problem. Considerable evidence suggests that CKD accelerates atherosclerosis, myocardial disease, and valvular disease and promotes an array of cardiac arrhythmias.³

Chronic Kidney Disease and Cardiovascular Risk

Chronic kidney disease is defined through a range of estimated glomerular filtration rate (eGFR) values derived from equations.⁴ A common definition for CKD stipulates an eGFR of less than 60 mL/min/1.73 m² or the presence of kidney damage (Fig. 88-2).

With age (as measured from 20 to 80 years), the eGFR declines from approximately 130 to 60 mL/min/1.73 m², a variety of pathobiologic processes appear to begin when the eGFR drops below 60 mL/min/1.73 m² (for an approximate serum creatinine level of 1.2 mg/dL in a woman and 1.5 mg/dL in a man). Most studies of cardiovascular outcomes have found this critical cut point for the development of contrast-induced acute kidney injury (CI-AKI), restenosis after percutaneous coronary intervention (PCI), recurrent acute myocardial infarction (AMI), diastolic or systolic heart failure, arrhythmias, and cardiovascular death.⁴⁻⁸ Because the serum creatinine is a crude

indicator of renal function and often underestimates renal dysfunction in women and the elderly, eGFR or creatinine clearance (CrCl) calculated by the Modification of Diet in Renal Disease (MDRD) equation and the Cockcroft-Gault equation, respectively, provide superior assessment of renal function.⁴ For epidemiologic studies, classification of disease, and prognosis, the four-variable MDRD equation for eGFR is preferred because it does not rely on body weight.⁴ The equation is $eGFR = (186.3 \times [\text{serum creatinine}^{-1.154}] \times [\text{age}^{-2.03}])$; calculated values are multiplied by 0.742 for women and by 1.21 for African Americans. The MDRD equation has been recently refined to the CKD-EPI (Chronic Kidney Disease Epidemiology Collaboration) equation for improved estimation of renal filtration and better prognostication of outcomes including progression of CKD and death. The CrCl is still used and preferred for renal drug dosing because it relies on actual body weight.

Cystatin C also reflects renal filtration function.⁹ Cystatin C is a nonglycosylated, low-molecular-mass (13-kDa) protein produced by all nucleated cells. Its low molecular mass and its high isoelectric point allow free filtration by the glomerulus and 100% reabsorption by the proximal tubule. The serum concentration of cystatin C correlates with eGFR and, in combination with a stable production rate, provides a sensitive marker of renal filtration function. Serum levels of cystatin C are independent of weight and height, muscle mass, age, or sex, making it less variable than serum creatinine. Furthermore, a single random sample measurement suffices, with reference intervals in women and men of 0.54 to 1.21 mg/L (median, 0.85 mg/L; range, 0.42 to 1.39 mg/L).

In addition, microalbuminuria at any level of eGFR indicates CKD, considered the result of endothelial dysfunction in glomerular capillaries secondary to the metabolic syndrome, diabetes mellitus, or hypertension.¹⁰ The most widely accepted definition of microalbuminuria is a random urine albumin-to-creatinine ratio (ACR) of 30 to 300 mg/g. An ACR greater than 300 mg/g is considered gross proteinuria. The random, spot ACR is the office test for microalbuminuria recommended as part of the cardiovascular risk assessment done by cardiologists and other specialists. Microalbuminuria independently predicts CVD for those with and without diabetes. The Chronic Kidney Disease Prognosis Consortium has demonstrated that both the eGFR and degree of albuminuria contribute independently to the risks of future acute kidney injury (AKI), progression of CKD, ESRD, nonfatal cardiovascular events, and death¹¹ (Fig. 88-3).

Implications of Anemia Due to Chronic Kidney Disease

There is increasing recognition of the association among blood hemoglobin (Hb) level, CKD, and CVD. The World Health

FIGURE 88-1 Normal structure of the glomerular vasculature. Each kidney contains approximately 1 million glomeruli in the renal cortex (**drawing A**). **Drawing B** shows an afferent arteriole entering Bowman's capsule and branching into several capillaries that form the glomerular tuft; the walls of the capillaries constitute the actual filter. The plasma filtrate (primary urine) is directed to the proximal tubule, whereas the unfiltered blood returns to the circulation through the efferent arteriole. The filtration barrier of the capillary wall contains an innermost fenestrated endothelium, the glomerular basement membrane, and a layer of interdigitating podocyte foot processes (**drawing C**). In **drawing D**, a cross section through the glomerular capillary depicts the fenestrated endothelial layer and the glomerular basement membrane with overlying podocyte foot processes. An ultrathin slit diaphragm spans the filtration slit between the foot processes, slightly above the basement membrane. To show the slit diaphragm, the foot processes are drawn smaller than actual scale. (Modified from Tryggvason K, Patrakka J, Wartiovaara J: Hereditary proteinuria syndromes and mechanisms of proteinuria. *N Engl J Med* 354:1387, 2006.)

Organization (WHO) definition of anemia is a Hb level below 13 g/dL in men and below 12 g/dL in women. Approximately 9% of the general adult population meets the definition of anemia at these levels. In general, anemia due to CKD is present in 20% of patients with stable coronary disease and 30% to 60% of patients with heart failure. Hence anemia is a common and easily identifiable potential cause of constitutional symptoms as well as a potential diagnostic and therapeutic target, particularly in children.^{12,13}

Anemia contributes to multiple adverse outcomes, in part owing to decreased tissue oxygen delivery and utilization.¹³ Of the many factors that may cause anemia in patients with CKD, of particular note is a relative deficiency of erythropoietin- α (EPO), an erythrocyte-stimulating protein (ESP), which normally is produced by renal parenchymal cells in response to decrease in blood partial pressure of oxygen. Normal plasma EPO levels range between 10 and 30 IU/mL; during anemic periods, however, these levels may be elevated

up to 100 IU/mL. Patients with CKD and heart failure appear to resist the effects of EPO. In addition, increased circulating levels of hepcidin, an inhibitor of the ferroportin receptor, impair iron absorption and utilization throughout the body including the bone marrow. These factors can work to directly reduce red cell production at the level of the bone marrow and further worsen the anemia. In a review, 28 of 29 large prospective studies of heart failure found anemia to predict mortality independently.¹⁴ As Hb drops over time, a graded increase in heart failure-related hospitalizations and death is seen. Conversely, those patients who have shown a spontaneous rise in Hb have fewer future events. This improvement is associated with a significant reduction in left ventricular mass index, suggesting a favorable change in left ventricular remodeling.¹⁵

Treatment of anemia with exogenous ESPs (EPO and darbepoetin α) increasing the Hb level from below 10 g/dL to 12 g/dL can improve left ventricular remodeling, ejection fraction, and functional

Criteria	
1. Kidney damage for ≥ 3 months, as defined by structural or functional abnormalities of the kidney, with or without decreased GFR, manifested by <i>either</i> : <ul style="list-style-type: none"> • Pathologic abnormalities; or • Markers of kidney damage, including abnormalities in the composition of the blood or urine, or abnormalities in imaging tests 	
2. eGFR <60 mL/min/1.73 m ² for ≥ 3 months, with or without kidney damage	

Markers of kidney damage	Findings indicating kidney damage
Proteinuria	Albuminuria
Urine sediment abnormalities	Cellular casts, coarse granular casts, fat
Imaging tests	Abnormalities in kidney size Asymmetry in kidney size or function Irregularities in shape (cysts, scars, mass lesions) Stones Hydronephrosis and other abnormalities of the urinary tract Arterial stenosis and other vascular lesions
Abnormalities in blood or urine composition	Nephrotic syndrome Tubular syndromes (renal tubular acidosis, potassium secretory defects, renal glycosuria, renal phosphaturia, Fanconi syndrome)

FIGURE 88-2 Diagnostic criteria for chronic kidney disease and kidney damage.

ALL-CAUSE MORTALITY

	ACR <10	ACR 10-29	ACR 30-299	ACR ≥ 300

FIGURE 88-3 As reported by the Chronic Kidney Disease Prognosis Consortium, relative risks of heart and kidney outcomes in cohorts in which eGFR and ACR were measured. (Modified from Chronic Kidney Disease Prognosis Consortium, Matsushita K, van der Velde M, et al: Association of estimated glomerular filtration rate and albuminuria with all-cause and cardiovascular mortality in general population cohorts: A collaborative meta-analysis. *Lancet* 375:2073, 2010.)

classification and raise levels of peak oxygen consumption with exercise testing. Yet treatment with EPO and supplemental iron (required in approximately 70% of cases), can cause three problems: (1) increased platelet activity, thrombin generation, and resultant increased risk of thrombosis; (2) elevated endothelin and asymmetric dimethylarginine which theoretically reduces nitric oxide availability, and results in hypertension; and (3) worsened measures of oxidative stress. Three randomized trials in CKD found that treatment with ESPs resulted in higher CVD event rate. The Cardiovascular Risk Reduction by Early Anemic Treatment with Epoetin beta in Chronic Kidney Disease Patients (CREATE) Trial randomly assigned 600 patients to treatment with EPO to a target Hb of 13.0 to 15.0 versus 10.5 to 11.5 g/dL over 2.5 years and found higher rates of CVD and progression to ESRD in the 13.0 to 15.0 g/dL group.¹⁶ The Correction of Hemoglobin and Outcomes in Renal Insufficiency (CHOIR) trial randomly assigned 1432 patient with CKD and treated with EPO to groups with a target of 13.5 g/dL or 11.3 g/dL.¹⁷ The composite endpoint of stroke, MI, heart failure-related hospitalization, and death occurred in 125 subjects in the 13.5 g/dL arm and in 97 in the 11.3 g/dL arm ($P = 0.03$). The Trial to Reduce Cardiovascular Events with Aranesp Therapy (TREAT) was a multicenter, double-blind, placebo-controlled study in 4038 patients with CKD (eGFR, 20 to 60 mL/min/1.73 m²), type 2 diabetes mellitus, and anemia (Hb <11 g/dL) that randomly assigned subjects to darbepoetin alfa to raise Hb to 13 g/dL versus placebo, with rescue therapy for Hb levels below 9 g/dL. Use of darbepoetin alfa was associated with higher rates of fatal or nonfatal stroke (hazard ratio [HR], 1.92; $P < 0.001$), with no differences

in rates of ESRD or death.¹⁸ Thus treatment of anemia with ESPs may actually worsen CVD outcomes in CKD. Therefore ESPs should be reserved for the treatment of severe anemia in CKD with the goal of improving symptoms and avoiding transfusion.

CONTRAST-INDUCED ACUTE KIDNEY INJURY

Definition and Pathophysiology

Iodinated CI-AKI is most commonly defined by the Acute Kidney Injury Network criteria of a 0.3 (mg/dL) or greater rise in serum creatinine from baseline within 48 hours of intravascular administration.¹⁹ CI-AKI occurs in approximately 13% in nondiabetics and 20% of those with diabetes mellitus undergoing PCI. The risk of CI-AKI relates in a curvilinear fashion to declining eGFR.²⁰ Fortunately, among patients undergoing PCI, CI-AKI leading to dialysis is rare (0.5% to 2.0%). Nevertheless, severe CI-AKI is associated with catastrophic outcomes including a 36% in-hospital mortality rate and a 2-year survival rate of only 19%.²¹ Transient rises in serum creatinine are associated with longer length of hospital stay, MI, stroke, heart failure, and rehospitalization, among other complications²² (Fig. 88-4).

Three core elements participate in the pathophysiology of CI-AKI: (1) direct toxicity of iodinated contrast material to nephrons, (2) microshowers of atheroemboli to the kidneys (consequent to catheter and wire exchanges above the renal arteries), and (3) contrast

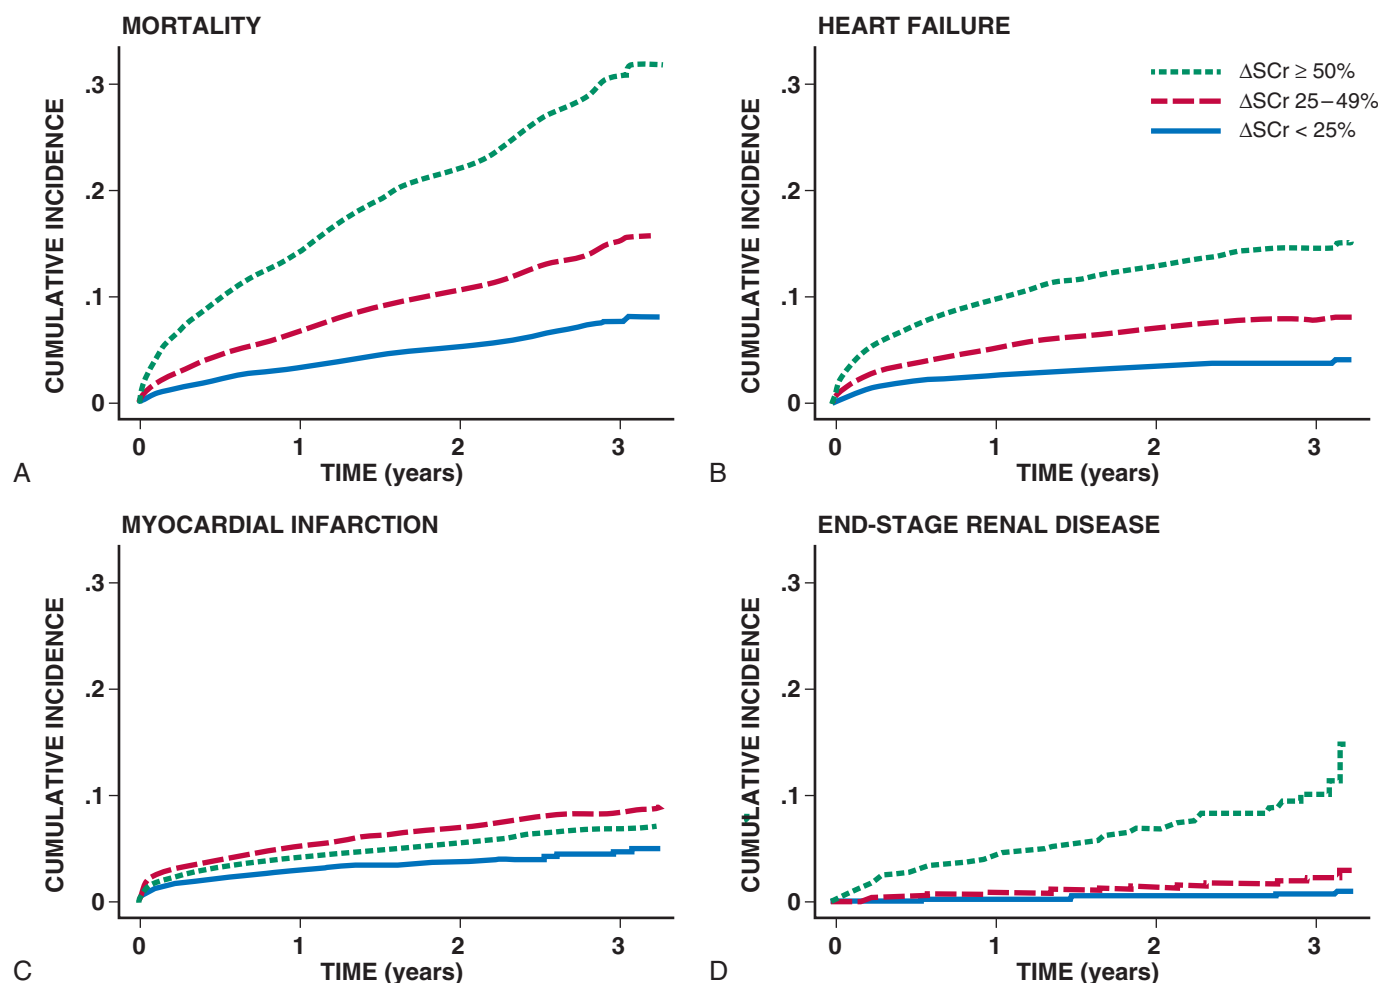

FIGURE 88-4 Cumulative incidence of all-cause mortality (A), hospitalization for heart failure (B), hospitalization for MI (C), and ESRD (D) after coronary angiography, according to severity of AKI as reflected by magnitude of change in serum creatinine (Δ SCr) concentration after coronary angiography. Number of procedures: coronary angiography alone = 4219; angiography with PCI = 8205; and angiography with cardiac surgery = 2412. (Modified from James MT, Ghali WA, Knudtson ML, et al: Associations between acute kidney injury and cardiovascular and renal outcomes after coronary angiography. *Circulation* 123:409, 2011.)

material- and atheroemboli-induced intrarenal vasoconstriction of the vasa recta. Direct toxicity to nephrons with iodinated contrast media appears to be related to the ionicity and osmolality of the contrast media.^{23,24} Microshowers of cholesterol emboli may contribute to AKI after PCI.²⁵ Most of these showers are clinically silent. In approximately 1% of high-risk cases, however, an acute cholesterol embolism syndrome can develop, manifested by acute renal failure, mesenteric ischemia, decreased microcirculation to the extremities, and, in some cases, embolic stroke (see Chapter 58). Because acute renal failure occurs after coronary artery bypass surgery with nearly the same risk predictors as CI-AKI, atheroembolism may contribute to both causes of renal failure.²⁶⁻²⁹ Hypoxia triggers activation of the renal SNS, further reducing renal blood flow (Fig. 88-5). Preexisting renal dysfunction leads as a predictor of CI-AKI. When the eGFR falls below 60 mL/min/1.73 m², the remaining nephrons must assume the residual filtration load, with increased oxygen demands and greater susceptibility to cytotoxic, ischemic, and oxidative injury.³⁰

Prevention of Contrast-Induced Acute Kidney Injury

Patients with baseline eGFR < 60 mL/min/1.73 m², in particular, those with CKD and diabetes mellitus, should receive preventive measures for CI-AKI. CKD, diabetes mellitus, and other risk factors including

hemodynamic instability, use of intra-aortic balloon counterpulsation, heart failure, older age, and anemia in the same patient can produce a predicted probability of CI-AKI of greater than 50%³¹ (Fig. 88-6). Thus obtaining informed consent for contrast procedures from patients at high risk for CI-AKI should include disclosure of this possibility. Four clinical issues merit consideration in CI-AKI prevention: (1) hydration and volume expansion, (2) choice and quantity of contrast material, (3) pre-, intra-, and postprocedural end-organ protection with pharmacotherapy, and (4) postprocedural monitoring and expectant care.

Hydration with intravenous normal saline or isotonic sodium bicarbonate is reasonable, starting 3 to 12 hours before the procedure at a rate of 1 to 2 mL/kg/hr.³²⁻³⁴ Patients at risk and able to tolerate the fluid load should receive at least 300 to 500 mL of intravenous hydration fluid before contrast administration. The largest trial (*N* = 381) of intravenous saline versus isotonic bicarbonate in elective angiography and PCI showed no differences in rates of CI-AKI (5.3% for saline, 9.0% for bicarbonate) or ESRD. Right-heart catheterization may aid management during and after the procedure for patients with heart failure. The postprocedure hydration target is a urine output of 150 mL/hr. Patients with urinary excretion rates of more than 150 mL/hr should have intravenous replacement of extra losses.³³ This strategy generally calls for normal saline or sodium bicarbonate at 150 mL/hr for at least 6 hours after the procedure.

FIGURE 88-5 Pathogenesis of CI-AKI. (Modified from Brown JR, McCullough PA: Contrast nephropathy and kidney injury. In Thompson CA [ed]: Textbook of Cardiovascular Intervention. New York, Springer, 2011.)

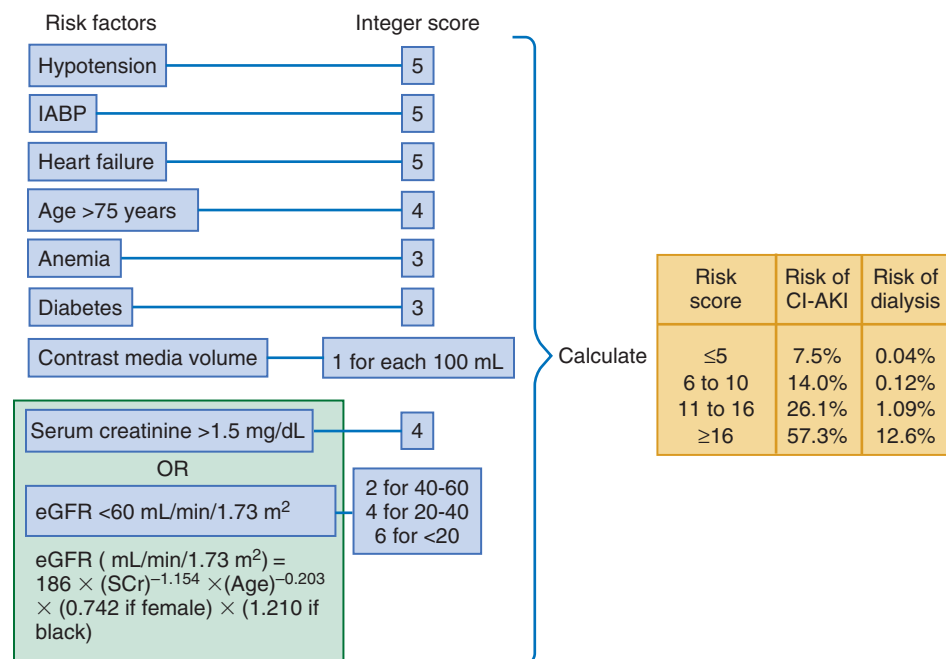

FIGURE 88-6 CI-AKI risk score. CI-AKI was defined as follows: 25% or 0.5 mg/dL increase from baseline pre-PCI serum creatinine at 48 hours after PCI. Anemia baseline hematocrit value: 39% for men and 36% for women. New York Heart Association class III/IV heart failure and/or history of pulmonary edema; hypotension systolic blood pressure 80 mm Hg for at least 1 hour requiring inotropic support with medications or intra-aortic balloon pump (IABP) within 24 hours of the periprocedural period. eGFR = estimated glomerular filtration rate. (Modified from Mehran R, Aymong ED, Nikolsky E, et al: A simple risk score for prediction of contrast-induced nephropathy after percutaneous coronary intervention: Development and initial validation. *J Am Coll Cardiol* 44:1393, 2004.)

Randomized trials of iodinated contrast agents have demonstrated the lowest rates of CI-AKI with nonionic, iso-osmolar iodixanol. A meta-analysis restricted to 25 head-to-head, prospective, double-blind, randomized, controlled trials that compared iodixanol with low-osmolar contrast media (LOCM) in adult patients undergoing angiographic examinations with serum creatinine values at baseline and after contrast administration.³⁵ The relative risk of CI-AKI (creatinine rise ≥ 0.5 mg/dL) occurring for iodixanol was 0.46 ($P = 0.004$), compared with LOCM, as summarized in **Figure 88-7**. These data support the hypothesis that iodixanol (290 mOsm/kg) is less nephrotoxic than LOCM agents with osmolalities ranging from 600 to 800 mOsm/kg when the intra-arterial route of administration is used. With intravenous administration, however, rates of CI-AKI do not differ between iso-osmolar contrast media (IOCM) and LOCM.³⁵

Contrast volume should be minimized in any setting, and there is disagreement about a “safe” contrast limit. The lower the eGFR, the smaller the amount of contrast material needed to cause CI-AKI. Maximum target volumes of contrast medium should be less than 30 mL for a diagnostic and less than 100 mL for an interventional procedure. With staged procedures, more than 10 days should elapse between the first and second contrast exposures if CI-AKI has occurred with the first procedure.

A majority of trials of preventive strategies for CI-AKI have been small and underpowered and did not find the preventive strategy under investigation to be better than placebo. These trials have yielded a few lessons: (1) loop diuretics or mannitol can worsen CI-AKI if volume replacement is inadequate for the diuresis that follows; (2) low-dose or “renal dose” dopamine or fenoldopam does not provide protection despite the popularity of this approach in clinical practice, given the counterbalancing forces of intrarenal vasodilation through the dopamine-1 receptor and the vasoconstricting forces of the dopamine-2, alpha, and beta receptors; and (3) renal toxic agents including nonsteroidal anti-inflammatory agents, aminoglycosides, and cyclosporine should not be administered in the periprocedural period. After many small, suggestive studies, a large ($N = 2308$) randomized trial of *N*-acetylcysteine 1200 mg by mouth twice daily the day before and after the procedure showed no differences

in the rates of CI-AKI (12.7% for both groups), ESRD, or other outcomes.³⁶ No agent has received U.S. Food and Drug Administration approval for the prevention of CI-AKI.

Figure 88-8 shows an algorithm for risk stratification and prevention of CI-AKI. It suggests for eGFR less than 60 mL/min/1.73 m² use of optimal hydration, iodixanol or LOCM as the contrast agent, and a concerted effort to minimize the contrast volume.³⁷ Postprocedural monitoring is critical in the current era of short stays and outpatient procedures. Ideally, in hospitalized high-risk patients, hydration should be started 12 hours before the procedure and continued for at least 6 hours afterward, with measurement of serum creatinine 24 hours after the procedure. Outpatients, particularly those with eGFR less than 60 mL/min/1.73 m², either are admitted for an overnight stay or can be discharged to home with 48-hour follow-up and serum creatinine measurement. Patients who will develop severe CI-AKI usually show a rise of creatinine greater than 0.5 mg/dL in the first 24 postoperative hours. Thus discharge to home for those with less serum creatinine elevation and an otherwise uncomplicated course may be considered. Those with eGFR less than 30 mL/min/1.73 m² require a discussion of the possibility of dialysis

and a nephrology consultation regarding possible pre- and postprocedure hemofiltration and dialysis management.³⁸

CARDIAC SURGERY–ASSOCIATED ACUTE KIDNEY INJURY

AKI occurs in approximately 15% of patients after forms of cardiac surgery with or without use of cardiopulmonary bypass. Higher rates of AKI can complicate surgery in patients who undergo coronary angiography within a few days preoperatively.³⁹ Mehta and colleagues have validated a risk prediction scheme for this complication⁴⁰ (**Fig. 88-9**). This scenario for AKI suggests that many factors including endogenous/exogenous toxins, metabolic factors, ischemia and reperfusion, neurohormonal activation, inflammation, and oxidative stress, all contribute to renal tubular injury heralded by reduced urine output and a rise in serum creatinine after cardiac surgery.⁴¹ The AKIN/RIFLE (Risk, Injury, Loss, Failure, End-stage Kidney Disease)/KDIGO (Kidney Disease Global Outcomes) criteria can establish AKI in this patient group (**Fig. 88-10**). In children undergoing cardiac surgery, urine neutrophil gelatinase associated lipocalin is markedly elevated in those who will go on to develop AKI. Other novel cardiac markers that are elevated in this scenario include urine kidney injury molecule 1, L-type fatty acid binding protein, alpha-glutathione S-transferase (alpha-GST), pi-GST, and other proteins that indicate renal tubular cell cycle arrest and apoptosis⁴² (**Fig. 88-11**). Off-pump cardiac surgery is associated with a reduction in the number of more severe cases of AKI. There are currently no established prophylactic or treatment measures for cardiac surgery–associated AKI.

ACCELERATION OF VASCULAR CALCIFICATION

At eGFR below 60 mL/min/1.73 m², the filtration and elimination of phosphorus fall. In addition, 1,25 dihydroxyvitamin D production decreases leading to relative hypocalcemia. Thus subtle degrees of hyperphosphatemia and hypocalcemia increase release of parathyroid hormone (PTH), causing liberation of calcium and phosphorus from bone. The bone in turn produces greater amounts of fibroblast growth factor-23, which directs the kidneys to increase the clearance of phosphorus. As a result of this abnormal bone and mineral metabolism, patients with ESRD have markedly increased absolute values and rates of accumulation of arterial calcium. A variety of in vitro stimuli can induce vascular smooth muscle cells to assume osteoblast-like functions in vitro, including handling of phosphorus, PTH, and PTH-related peptide (**Fig. 88-12**). Clinical studies in ESRD suggest that the degree

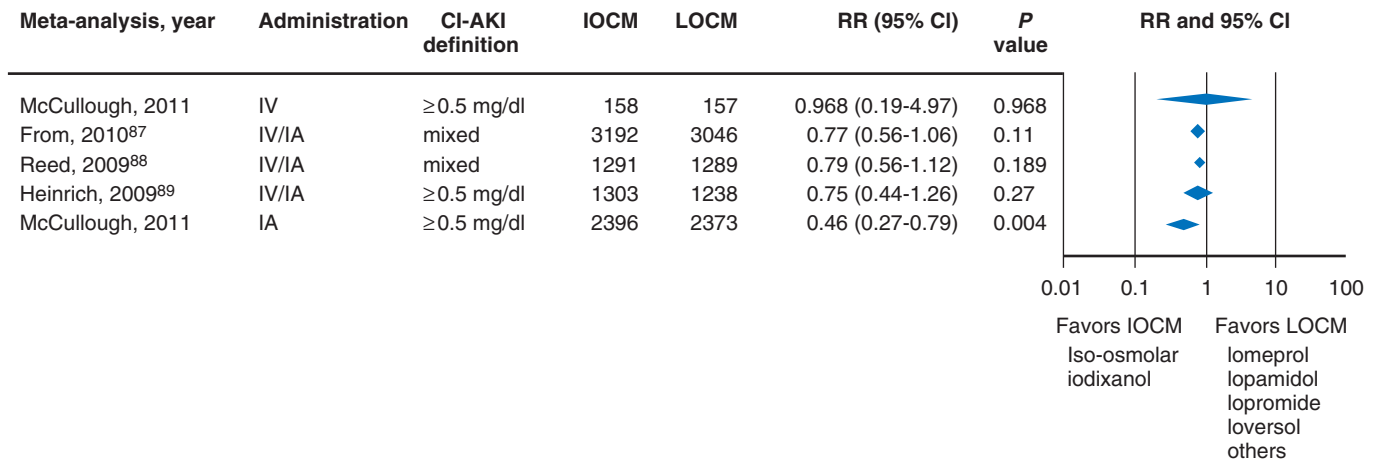

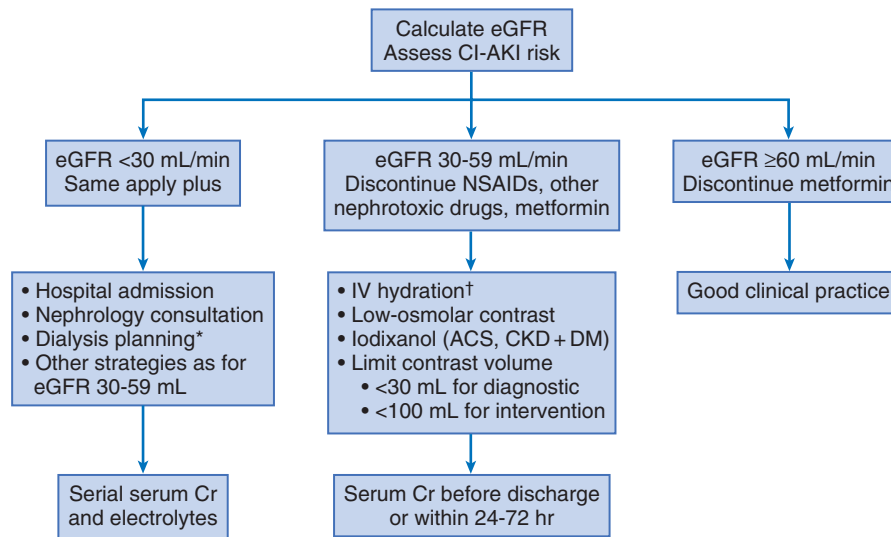

FIGURE 88-7 Compilation of pooled odds ratios from head-to-head trials for intra-arterial (IA), intravenous (IV), and mixed IA and IV meta-analyses of the incidence of CI-AKI (defined as ≥0.5 mg/dL increase in serum creatinine from baseline) demonstrating a leftward shift in pooled estimates moving from IV to mixed IV/IA, and IA trials favoring the use of iodixanol. RR = relative risk. (Modified from McCullough PA, Brown JR: Effects of intra-arterial and intravenous iso-osmolar contrast medium (iodixanol) on the risk of contrast-induced acute kidney injury: A meta-analysis. *Cardiorenal Med* 1:220, 2011.)

*Plans should be made in case CI-AKI occurs and dialysis is required.

†IV isotonic crystalloid 1-1.5 mL/kg/hr for 3-12 hr before and 6-24 hr after the procedure.

FIGURE 88-8 Algorithm for management of patients receiving iodinated contrast media. ACS = acute coronary syndrome; Cr = creatinine; DM = diabetes mellitus; IV = intravenous; NSAIDs = nonsteroidal anti-inflammatory drugs. (Modified from McCullough PA: Contrast-induced acute kidney injury. *J Am Coll Cardiol* 51:1419, 2008.)

of vascular calcification depends on age, length of time on dialysis, and dyslipidemia.⁴³

Multiple randomized trials have compared non-calcium-based phosphate binders (e.g., sevelamer, a gastrointestinal phosphate binder with a similar structure to the bile acid-binding resin colesevelam) and calcium based binders (calcium carbonate or calcium acetate), measuring the change in coronary artery calcification (CAC) by computed tomography scans done at baseline and at 52 weeks.⁴⁵ In general, no specific strategy has changed the annual rate of increase in CAC score. These rates pooled from 10 trials were 16.9% and 18.4% in general and CKD populations, respectively.⁴⁵ Treatments for secondary hyperparathyroidism include cinacalcet, a calcimimetic agent that modifies the calcium-sensing receptor on parathyroid cells, and vitamin D analogues, which reduce nuclear transcription of PTH. The ADVANCE study (A randomised Vascular calcification study to evaluate the effects of CinacalcEt) randomly assigned hemodialysis patients with PTH greater than 300 pg/mL or PTH 150 to 300 pg/mL with calcium-phosphorus product > 50 mg²/dL² while receiving calcium-based phosphate binders to receive cinacalcet (30 to 180 mg/day) plus low-dose calcitriol or vitamin D

analogue (≤2 µg paricalcitol equivalent/dialysis session) versus flexible vitamin D therapy.⁴⁶ The median CAC scores increased 24% in the cinacalcet group and 31% in the flexible vitamin D group ($P = 0.07$). The EVOLVE (EValuation Of Cinacalcet HCl Therapy to Lower Cardio-Vascular Events) trial, randomly assigned 3883 patients who had ESRD with secondary hyperparathyroidism to receive cinacalcet versus placebo, and despite lowering PTH, a modest age-adjusted reduction was noted in the primary composite of all-cause mortality, AMI, hospitalization for unstable angina, heart failure, or peripheral vascular event with the use of oral cinacalcet.⁴⁷ Thus no strategies studied that manipulate calcium-phosphorus balance or treat secondary hyperparathyroidism significantly influence the progression of coronary calcification or decrease cardiovascular events in patients with ESRD.

RENAL DISEASE AND HYPERTENSION

The kidney regulates blood pressure and controls intraglomerular pressure through autoregulation. Sodium retention stimulates

AKI is defined as any of the following:

- Increase in SCr by ≥ 0.3 mg/dL (≥ 26.5 μ mol/liter) within 48 hours; or
- Increase in SCr to ≥ 1.5 times baseline, which is known or presumed to have occurred within the previous 7 days; or
- Urine volume <0.5 mL/kg/h for 6 hours.

AKI is staged for severity according to the following criteria

STAGING OF AKI

Stage	Serum creatinine	Urine output
1	1.5-1.9 times baseline OR ≥ 0.3 mg/dL (≥ 26.5 μ mol/liter) increase	<0.5 mL/kg/h for 6-12 hours
2	2.0-2.9 times baseline	<0.5 mL/kg/h for ≥ 12 hours
3	3.0 times baseline OR Increase in serum creatinine ≥ 4.0 mg/dL (≥ 353.6 μ mol/liter) OR Initiation of renal replacement therapy OR, in patients <18 years, decrease in eGFR to <35 mL/min/1.73 m ²	<0.3 mL/kg/h for ≥ 24 hours OR Anuria for ≥ 12 hours

increases in systemic and renal arteriolar pressure in an attempt to force greater degrees of filtration in the glomerulus. Glomerular injury activates several pathways that can increase systemic blood pressure. This effect sets up a vicious circle of more glomerular and tubulointerstitial injury and worsened hypertension (**see also Chapters 43 and 44**). A cornerstone of management of combined CKD and CVD is strict blood pressure control with a target of less than 130/80 mm Hg (**Fig. 88-13**). Most patients with CKD and proteinuria require three or more antihypertensive agents to achieve this goal blood pressure.⁴⁸ Lifestyle management priorities for CKD and hypertension include dietary changes with sodium restriction, weight reduction of 15% or more to a target body mass index less than 25 kg/m², and exercise for 60 minutes/day most days of the week. Pharmacologic therapy aims for strict blood pressure control with an agent that antagonizes the RAAS, often in combined action with a thiazide-type diuretic.⁴⁸ Dihydropyridine calcium channel blocker monotherapy should be avoided because of relative afferent arteriolar dilation increased intraglomerular pressure and worsen glomerular injury. Combinations of multiple RAAS-blocking drugs—angiotensin-converting enzyme (ACE) inhibitor, angiotensin receptor blocker (ARB), direct renin inhibitor—have not shown superiority to single agents in this class and cause more complications. Clinical clues suggest underlying bilateral renal artery stenosis (e.g., poorly controlled blood pressure on more than three agents, abdominal bruits, smoking history, peripheral arterial disease, or a marked change in serum creatinine with administration of ACE inhibitor or ARB).⁴⁹ Although renal artery stenosis accounts for less than 3% of ESRD cases, it represents a potentially treatable condition.⁵⁰ Diagnostic and advanced therapeutic approaches for renal artery stenosis are discussed elsewhere in this text. Percutaneous renal artery denervation is undergoing evaluation as an approach to, lessen need for antihypertensive agents, and may improve cardiovascular outcomes (**see Chapters 43, 44, and 60**).⁵¹

DIAGNOSIS OF ACUTE CORONARY SYNDROMES IN PATIENTS WITH CHRONIC KIDNEY DISEASE

Patients with CKD have higher rates of silent ischemia, risk of serious arrhythmias, heart failure, and other cardiac complications. In stable outpatients with CKD, 38% and 68% will have a high-sensitivity cardiac troponin I (cTnI) and cardiac troponin T (cTnT) above the 99th percentile of normal, respectively. The degree of elevation of cTn reflects left ventricular mass and the severity of renal disease.⁵² The cTnI predicts mortality in patients with ESRD.⁵³ In general, cTnI serves best for diagnostic evaluation of patients with CKD or ESRD experiencing acute chest discomfort, whereas chronic elevations of cTnT are more common and more prognostic in stable patients. A rise and fall of cTnI or cTnT above the 99th percentile aids in the diagnosis of AMI in patients with CKD or ESRD. The skeletal myopathy of CKD can elevate creatine kinase, myoglobin, and some older-generation cTnI/cTnT assays, making these tests less desirable. Beyond biomarkers, the diagnosis of AMI should include confirmation of characteristic chest pain, electrocardiographic changes (ST-segment elevation or depression, new Q waves), or perfusion abnormalities or the identification of a culprit lesion on angiography.

Renal Dysfunction as a Prognostic Factor in Acute Coronary Syndromes

Many advances have ameliorated the diagnosis and treatment of acute coronary syndromes (ACSs) in the general population (**Tables 88-1 to 88-3**) (**see also Chapters 52 and 53**). Patients with CKD represent 30.5% of STEMI cases and 42.9% of NSTEMI cases (**Fig. 88-14**), and CKD is associated with higher rates of in-hospital mortality in a graded fashion with worsened renal function⁵⁴ (**Fig. 88-15**).

Data from clinical trials and observational studies consistently support the independent association between degree of CKD and 30-day and 1-year mortality after ACS.⁵⁵ In addition to mortality, reduced baseline eGFR predicts higher rates of AKI, bleeding, the development of heart failure, recurrent MI, rehospitalization, and stroke in the setting of ACS. Patients with ESRD have the highest mortality after AMI of any large, chronic disease population.

Reasons for Poor Outcomes after Acute Coronary Syndromes in Patients with Renal Dysfunction

Four reasons may explain why patients with renal dysfunction have poor cardiovascular outcomes after ACS: (1) excess comorbid conditions associated with CKD and ESRD, in particular, diabetes mellitus and left ventricular dysfunction; (2) therapeutic nihilism; (3) toxicity of therapies; and (4) special biologic and pathophysiologic factors in renal dysfunction that cause worsened outcomes.⁵⁶

The defects in thrombosis attributable to uremia include excess thrombin generation and decreased platelet aggregation.⁵⁷ Hence, patients with CKD and ESRD can have increased rates of coronary thrombotic events and increased bleeding risks at the same time. In patients with renal dysfunction the risks of bleeding increase with aspirin, unfractionated heparin, low-molecular-weight heparin, thrombolytics, glycoprotein IIb/IIIa antagonists, and thienopyridine antiplatelet agents (**Tables 88-4 and 88-5**).

TABLE 88-1 Acute and Chronic Treatments for CAD in Patients with Chronic Kidney Disease

MEDICATION	NORMAL DOSE	DOSING CONSIDERATIONS IN CKD POPULATION	PHARMACOLOGY
Antiplatelet Agents			
Aspirin	Acute MI: 160-325 mg by mouth as soon as possible MI prophylaxis: 81-162 mg by mouth once daily PCI: 325 mg by mouth 2 hr presurgery, then 160-325 mg by mouth maintenance UA: 75-162 mg by mouth once daily	No specific dosing adjustments in patients with CKD Meta-analysis involving patients on dialysis demonstrated a benefit of aspirin therapy on cardiovascular outcomes	<i>Metabolism:</i> liver, microsomal enzyme system <i>Renal clearance:</i> 80%-100% 24-72 hr <i>Excretion:</i> principally in urine (80%-100%), sweat, saliva, feces
Clopidogrel	UA/NSTEMI: 300-600 mg initial loading dose, followed by 75 mg by mouth once daily with aspirin STEMI: 75 mg by mouth once daily with aspirin 75-162 mg per day Recent MI: 75 mg by mouth once daily	No specific dosing adjustments in patients with CKD	<i>Metabolism:</i> CYP3A4, CYP2C19 (predominantly) and others to generate active metabolite; also by esterase to an inactive metabolite <i>Excretion:</i> urine and feces
Prasugrel	ACS: <i>Loading dose:</i> 60 mg by mouth <i>Maintenance dose:</i> 10 mg by mouth once daily with aspirin 81-325 mg/day; bleeding risk may increase if weight <60 kg, consider 5 mg by mouth once daily (efficacy/safety not established)	No specific dose adjustments in patients with CKD	<i>Metabolism:</i> liver; CYP450, CYP2B6, CYP2C9/CYP2C19 (minor), CYP3A4 substrate; CYP2B6 (weak) inhibitor <i>Excretion:</i> urine (68%) and feces (27%)
Ticagrelor	ACS with PCI and stent: <i>Starting dose:</i> 180 mg by mouth once <i>Maintenance dose:</i> 90 mg by mouth twice daily To be given for 1 year with aspirin as an alternative option for dual-antiplatelet therapy	No specific dose adjustments in patients with CKD	<i>Metabolism:</i> hepatic CYP450 <i>Excretion:</i> bile primarily, urine <1%
Angiotensin-Converting Enzyme Inhibitors			
<i>Examples:</i> captopril, zofenopril, enalapril, ramipril, quinapril, perindopril, lisinopril, benazepril, imidapril, trandolapril, fosinopril	Indicated for treatment of hypertension, prevention of cardiovascular events including heart failure in persons at risk, limiting progression of type 1 diabetic nephropathy, and reduction in cardiovascular events in patients after MI with left ventricular dysfunction or heart failure Also indicated for treatment of heart failure	Dosing schedules may need to be individualized for each dialysis session to avoid intradialytic hypotension In general, reduce dose by 50%-75% in ESRD	<i>Elimination:</i> mainly renal, with an elimination half-life of 12.6 hr in healthy persons In patients with impaired renal function (CrCl ≤30 mL/min), a longer half-life and accumulation have been observed without clinical consequences
Angiotensin II Receptor Antagonists			
<i>Examples:</i> losartan, irbesartan, olmesartan, candesartan, valsartan, telmisartan	Indicated for treatment of hypertension, to limit the progression of type 2 diabetic nephropathy, and to reduce cardiovascular events in patients after MI with left ventricular dysfunction or heart failure Indicated for heart failure in those intolerant to ACE inhibitors	As first-line treatment in most patients with CKD, we recommend the use of ACE inhibitors or ARBs; both have been shown to reduce LVH in patients on hemodialysis Levels of ARBs do not change significantly during hemodialysis	Losartan: 88% hepatic and 12% renal clearance
Calcium Channel Blockers (CCBs)			
Dihydropyridines <i>Examples:</i> amlodipine, felodipine, nicardipine, nifedipine, nimodipine, nitrendipine Nondihydropyridines <i>Examples:</i> diltiazem, verapamil	In UA/NSTEMI, if beta blockers are contraindicated, a nondihydropyridine CCB should be chosen in the absence of clinically significant left ventricular dysfunction or other contraindications ⁴⁴	No specific dose adjustments for patients with CKD Management of chronic CAD in patients on dialysis should follow that for the general population and use of CCBs as indicated The hemodynamic and electrophysiologic effects of individual CCBs are markedly different from those of each other and should be evaluated in selecting a suitable therapy	Amlodipine: renal elimination is the major route of excretion, with ~60% cleared in the urine Diltiazem: undergoes primary liver metabolism

**TABLE 88-1 Acute and Chronic Treatments for CAD in Patients with Chronic Kidney Disease—cont'd**

MEDICATION	NORMAL DOSE	DOSING CONSIDERATIONS IN CKD POPULATION	PHARMACOLOGY
Nitrates			
Nitroglycerin	2% ointment Angina: 0.5-2 inches applied in morning and 6 hr later to truncal skin Heart failure: 1.5 inches, which may be increased by 0.5-1 inch up to 4 inches, every 4 hr <i>Sublingual</i> : 0.4 mg for relief of chest pain in ACS: <i>Sublingual</i> : 0.3-0.6 mg every 5 min <i>Maximum</i> : 3 doses within 15 min	No specific dose adjustments for patients with CKD Care must be used to avoid hypotension in low-volume states such as dialysis sessions	<i>Metabolism</i> : mainly in liver, extrahepatic sites such as vascular wall, red blood cells <i>Excretion</i> : urine
Antianginal Agents			
Ranolazine	500-1000 mg by mouth twice daily <i>Maximum</i> : 2000 mg per day	Contraindicated in CrCl <30 mL/min Prolongs QTc interval Close monitoring recommended	<i>Excretion</i> : urine 73%-75%, feces 25%

CAD = coronary artery disease; LVH = left ventricular hypertrophy; NSTEMI = non-ST-segment elevation myocardial infarction; STEMI = ST-elevation myocardial infarction; UA = unstable angina.

TABLE 88-2 Beta-Adrenergic Receptor Blockers in Patients with Chronic Kidney Disease*

MEDICATION	NORMAL DOSE	DOSING CONSIDERATIONS IN CKD POPULATION	PHARMACOLOGY
Metoprolol	Acute MI: Metoprolol tartrate: 2.5-5 mg rapid IV every 2-5 min, up to 15 mg over 10-15 min, then 15 min after last infusion and receiving 15 mg IV or 50 mg by mouth q6h for 48 hr, then 50-100 mg by mouth twice daily Angina: Metoprolol tartrate: initially 50 mg by mouth twice daily, then titrated to 200 mg by mouth twice daily Metoprolol succinate: 100 mg by mouth once daily; no more than 400 mg per day	No specific dose adjustments for patients with CKD Close monitoring for adverse effects recommended	<i>Dialyzable</i> : Yes <i>Metabolism</i> : hepatic CYP2D6 <i>Metabolites</i> : inactive <i>Excretion</i> : urine 95%
Esmolol	<i>Immediate control</i> : For intraoperative treatment give bolus dose of 80 mg (approximately 1 mg/kg) over 30 s, followed by infusion of 150 µg/kg/min, if needed <i>Maximum infusion rate</i> : 300 µg/kg/min <i>Gradual control</i> : For postoperative treatment, give loading dose infusion of 500 µg/kg/min over 1 min followed by a 4-min infusion of 50 µg/kg/min If no effect within 5 min, repeat loading dose and follow with infusion increased to 100 µg/kg/min	No specific dose adjustments for patients with CKD	<i>Metabolism</i> : extensively metabolized by esterase in cytosol of red blood cells <i>Metabolites</i> : major acid metabolite (ASL-8123), methanol (inactive) <i>Excretion</i> : urine <1%-2%
Carvedilol	Hypertension and post-MI protection: 6.25-25 mg by mouth twice daily Start at 6.25 mg by mouth twice daily; then increase every 3-14 days to 12.5 mg by mouth twice daily, then 25 mg by mouth twice daily	No specific dose adjustments for patients with CKD In a small study of patients on dialysis with dilated cardiomyopathies, carvedilol improved left ventricular function and decreased hospitalization, cardiovascular deaths and total mortality.	<i>Elimination</i> : mainly biliary <i>Excretion</i> : primarily via feces

*Hemodialysis reduces blood levels of atenolol, acebutolol, and nadolol; by contrast, levels of carvedilol and labetalol do not change significantly.
IV = intravenous.

TABLE 88-3 Lipid-Lowering Therapy for Primary and Secondary Prevention in Patients with Chronic Kidney Disease

MEDICATION	NORMAL DOSE	DOSING CONSIDERATIONS IN CKD POPULATION	PHARMACOLOGY
Simvastatin	Cardiovascular event protection: 20-40 mg by mouth once daily combined with ezetimibe 10 mg by mouth once daily <i>Maximum dose:</i> 40 mg by mouth given at hour of sleep	Consider starting dose at 5 mg in the evening in patients with CKD In SHARP, lipid lowering with statin + ezetimibe was beneficial in patients with CKD In HPS, simvastatin reduced the renal decline in patients with CKD	<i>Metabolism:</i> liver, CYP450 <i>Excretion:</i> bile primarily, urine <2%
Atorvastatin	Cardiovascular event protection: 10-80 mg by mouth once daily	No specific dose adjustments for patients with CKD Use of atorvastatin 10 mg in patients with CKD was associated with a significantly lower risk of the primary endpoint (nonfatal MI or cardiac death) when compared with placebo. In the TNT and GREACE studies, atorvastatin showed improvement in renal function in patients with CKD.	<i>Metabolism:</i> liver, CYP450 <i>Excretion:</i> bile primarily, urine <2%
Fluvastatin	Cardiovascular event protection: 40 mg by mouth twice daily <i>Extended release:</i> 80 mg by mouth once daily	No specific dose adjustments for patients with CKD Caution for increased risk of rhabdomyolysis A multicenter, randomized, double blind, placebo-controlled trial of fluvastatin was conducted in kidney transplant recipients. Fluvastatin reduced LDL cholesterol levels by 32%. Although the primary endpoint did not achieve statistical significance, secondary analysis showed that the fluvastatin group experienced fewer cardiac deaths and nonfatal MI compared with the placebo group. Coronary intervention procedures were not significantly different between the two groups.	<i>Excretion:</i> feces 90%, urine 5%
Pravastatin	Cardiovascular event protection: <i>Start:</i> 40 mg by mouth once daily; may adjust dose every 4 weeks <i>Maximum dose:</i> 80 mg by mouth once daily	Start at 10 mg by mouth once daily in patients with CKD. In a randomized trial of pravastatin versus placebo in patients with previous MI and CKD, ⁸² secondary analysis showed that rates for coronary death or nonfatal MI were lower in patients receiving pravastatin, suggesting that pravastatin is effective for secondary prevention of cardiovascular events in patients with CKD.	<i>Excretion:</i> feces 70%, urine 20%

FIGURE 88-14 Prevalence of CKD stages 3a, 3b, 4, and 5 (no dialysis) and dialysis manifesting with STEMI and NSTEMI. Stage 3b was defined as eGFR 30 to 44 mL/min/1.73 m²; stage 4 CKD as an eGFR between 15 and 29 mL/min/1.73 m², and stage 5 CKD as eGFR less than 15 mL/min/1.73 m² or need for dialysis therapy. (Modified from Fox CS, Muntner P, Chen AY, et al: Use of evidence-based therapies in short-term outcomes of ST-segment elevation myocardial infarction and non-ST-segment elevation myocardial infarction in patients with chronic kidney disease: A report from the National Cardiovascular Data Acute Coronary Treatment and Intervention Outcomes Network registry. *Circulation* 121:357, 2010.)

FIGURE 88-15 Crude rates and adjusted odds ratios (ORs) for death by CKD stages among those presenting with STEMI and NSTEMI, with P_{trend} and $P_{\text{interaction}}$ for STEMI versus NSTEMI by CKD stages. Stage 3a CKD was defined as an eGFR between 45 and 59 mL/min/1.73 m²; stage 3b as eGFR 30 to 44 mL/min/1.73 m²; stage 4 CKD as eGFR between 15 and 29 mL/min/1.73 m², and stage 5 CKD as eGFR below 15 mL/min/1.73 m² or need for dialysis therapy. (Modified from Fox CS, Muntner P, Chen AY, et al: Use of evidence-based therapies in short-term outcomes of ST-segment elevation myocardial infarction and non-ST-segment elevation myocardial infarction in patients with chronic kidney disease: A report from the National Cardiovascular Data Acute Coronary Treatment and Intervention Outcomes Network registry. *Circulation* 121:357, 2010.)

TABLE 88-4 Intravenous Glycoprotein IIb/IIIa Inhibitors for Patients with Unstable Angina/NSTEMI and STEMI

AGENT	NORMAL DOSE	DOSING CONSIDERATIONS IN CKD POPULATION	PHARMACOLOGY
Abciximab	Adjunct to PCI: 0.25 mg/kg IV bolus over at least 1 min, 10-60 min before start of PCI, then 0.125 µg/kg/min (not to exceed 10 µg/min) continuous IV infusion for 12 hr Unstable angina with PCI planned within 24 hr: 0.25 mg/kg IV bolus over at least 1 min, then 0.125 µg/kg/min (not to exceed 10 µg/min) IV infusion for 18-24 hr concluding 1 hr after PCI	No specific dose adjustments for patients with CKD Abciximab also should be considered for adjunctive therapy in patients with ACS on dialysis In CKD, safety of abciximab has been shown for creatinine levels >1.72 mg/dL Although increased bleeding with abciximab in patients with CKD has been reported, other studies have shown no increase in bleeding for CKD versus no CKD for abciximab in PCI	<i>Metabolism:</i> unknown, but probably by the reticuloendothelial system; <i>CYP450:</i> unknown involvement <i>Excretion:</i> urine
Eptifibatide	ACS: 180 µg/kg IV bolus, then 2 µg/kg/min IV for up to 72 hr PCI: 180 µg/kg IV, then a continuous infusion at 2 µg/kg/min with another 180 µg/kg IV bolus 10 min after first bolus Continue infusion for at least 12 hr	CrCl <50 mL/min and ACS: 180 µg/kg IV, then continuous infusion 1 µg/kg/min Safety and use during hemodialysis not established	<i>Metabolism:</i> minimal hepatic; <i>CYP450:</i> unknown involvement <i>Excretion:</i> urine 50%
Tirofiban	In patients undergoing PCI, tirofiban is not recommended as an alternative to abciximab ⁴³ ACS: 0.4 µg/kg/min IV for 30 min, then 0.1 µg/kg/min IV for 48-108 hr PCI: Continue 0.1 µg/kg per min IV through procedure and for 12-24 hr afterward	CrCl <30 mL/min and ACS: reduce dose to 50% of normal rate Safety and use during hemodialysis not established	<i>Excretion:</i> urine 65% (primarily unchanged), feces 25% (primarily unchanged)

*When a glycoprotein IIb/IIIa antagonist is used, abciximab and tirofiban should be considered preferred agents, because no dosing changes are required for abciximab, and dialysis-specific dosing recommendations are available for tirofiban. Increased bleeding but reduced in-hospital mortality in patients with CKD with ACS treated with glycoprotein IIb/IIIa antagonists also have been shown.⁴⁹

IV = intravenous; NSTEMI = non-ST-segment elevation myocardial infarction; STEMI = ST-elevation myocardial infarction.

TABLE 88-5 Antithrombotic Agents for ACS and Other Thrombotic Indications in Patients with Chronic Kidney Disease

AGENT	NORMAL DOSE	DOSING CONSIDERATIONS IN CKD POPULATION	PHARMACOLOGY
Indirect factor Xa Inhibitors			
Unfractionated heparin	Recommended dosage and desired aPTT values as per institutional protocol PCI: 60-100 units/kg IV given once Target ACT: 250-350 s In patients receiving glycoprotein IIb/IIIa inhibitor, give 50-70 units/kg IV to target ACT of 200 s STEMI, adjunct treatment, streptokinase use: 800 units/hr with body weight <80 kg or 1000 units/hr with body weight >80 kg Start: 5000 units IV, adjust dose to target aPTT of 50-75 s NSTEMI: 12-15 units/kg/hr IV Start: 60-70 units/kg IV, to maximum of 5000 units, as bolus Maximum rate: 1000 units/hr Adjust dose to target aPTT of 50-75 s	In patients with CKD, suggested starting dose of heparin is 50 IU/kg bolus, then 18 IU/kg/hr Monitor aPTT level and adjust accordingly as per institutional protocol	Metabolism: liver (partial) Metabolites: none Excretion: urine
Low-molecular-weight heparin (e.g. enoxaparin)	Unstable angina, non-Q-wave myocardial infarction: 1 mg/kg subcutaneously twice daily STEMI, in patient <75 years of age: 30 mg IV bolus plus 1 mg/kg subcutaneously, then 1 mg/kg subcutaneously q12h PCI: additional 0.3 mg/kg IV bolus if last subcutaneous administration given >8 hr before balloon inflation STEMI, in patients ≥75 years of age: 0.75 mg/kg subcutaneously q12h (no IV bolus)	CrCl <30 mL/min: STEMI, in patients <75 years of age: 30 mg IV bolus plus 1 mg/kg subcutaneously, then 1 mg/kg subcutaneously once a day STEMI, in patients ≥75 years of age: 1 mg/kg subcutaneously once a day	Excretion: urine 40%
Direct Factor Xa Inhibitor			
Fondaparinux	Unstable angina/NSTEMI: Conservative strategy: 2.5 mg subcutaneously once daily During PCI: add unfractionated heparin 50-60 units/kg IV bolus for prophylaxis of catheter thrombosis ⁴⁹	CrCl 30-50 mL/min: use with caution CrCl <30 mL/min: not indicated	Excretion: urine (primarily unchanged)
Direct Thrombin Inhibitors			
Bivalirudin	Intended for use with aspirin 300-325 mg/day 0.75 mg/kg IV bolus initially, followed by continuous infusion at rate of 1.75 mg/kg/hr for duration of procedure Determine ACT 5 min after bolus dose Administer additional 0.3 mg/kg bolus if necessary May continue infusion after PCI beyond 4 hr (optional post-PCI, at discretion of treating health care provider) initiated at rate of 0.2 mg/kg/hr for up to 20 hr as needed	CrCl 10-29 mL/min: usual bolus dose, then initial infusion of 1 mg/kg/hr IV up to 4 hr Hemodialysis: usual bolus dose, then initial infusion of 0.25 mg/kg/hr IV up to 4 hr Bivalirudin is a direct thrombin inhibitor with specific dosing adjustments for patients on dialysis and should be preferentially considered	Dialyzable: with 25% reduction in levels Excretion: urine
Dabigatran	Indicated for prevention of stroke and thromboembolism associated with nonvalvular atrial fibrillation CrCl >30 mL/min: 150 mg by mouth twice daily	CrCl 15-30 mL/min: 75 mg by mouth twice daily CrCl <15 mL/min or hemodialysis: not indicated For patients currently taking dabigatran, wait 12 hr (with CrCl ≥30 mL/min) or 24 hr (with CrCl <30 mL/min) after last dose of dabigatran before initiating treatment with a parenteral anticoagulant If possible, discontinue dabigatran 1-2 days (with CrCl ≥50 mL/min) or 3-5 days (with CrCl <50 mL/min) before invasive or surgical procedures because of increased risk of bleeding	Excretion: urine 7%, feces 86%
Rivaroxaban	Indicated for prevention of stroke and thromboembolism associated with nonvalvular atrial fibrillation, venous thromboembolism (VTE) CrCl >50 mL/min: 15 mg by mouth twice daily for 3 weeks (acute anticoagulation for VTE) CrCl >50 mL/min: 20 mg by mouth at bedtime (chronic anticoagulation)	CrCl 15-50 mL/min: 15 mg by mouth at bedtime CrCl <15 mL/min: not indicated	Metabolism: liver CYP450 Excretion: urine 66%, feces 28% Half-life: 5-9 hr or 11-13 hr in elderly

ACT = activated clotting time; aPTT = activated partial thromboplastin time; IV = intravenous; NSTEMI = non-ST-segment elevation myocardial infarction; STEMI = ST-elevation myocardial infarction.

Uremia causes platelet dysfunction by a mechanism that is independent of and therefore additive to pharmacologically induced platelet antagonism or antithrombosis.⁵⁸ In patients with renal dysfunction, the best measure of bleeding risk is the bleeding time. Because bleeding time is not a practical test in ACSs, clinicians cannot readily assess the a priori bleeding risk for any given patient with CKD or ESRD. Bleeding complications probably do not account for all of the large differences in mortality between patients with CKD and ESRD and those with preserved renal function with ACS.

Renal dysfunction promotes inflammation and is associated with higher rates of thrombotic CVD events. Hyperactivation of neurohormonal signaling by the RAAS, SNS, endothelin, and vasopressin, with inadequate balance by natriuretic peptides and nitric oxide, may worsen ischemia, myocardial dysfunction, and end-organ injury.

Treatment of Myocardial Infarction in Patients with Renal Dysfunction

Therapies for ACS that are of benefit in the general population often yield enhanced benefit in patients with CKD and ESRD. Data support a favorable benefit-to-risk ratio for aspirin, beta-adrenergic blocking agents (beta blockers), ACE inhibitors, ARBs, aldosterone receptor antagonists, and statins.⁵⁹ Therapies that require dose adjustment on the basis of CrCl include low-molecular-weight heparins, bivalirudin, and glycoprotein IIb/IIIa antagonists (see [Tables 88-4](#) and [88-5](#)).⁵⁸ Greater use of such therapies, despite the heightened risk for complications, might attenuate the excess mortality reported in CKD and ESRD populations. Although randomized trials of PCI in patients with CKD or ESRD are lacking, the large Swedish Web-system for Enhancement and Development of Evidence-based care in Heart disease Evaluated According to Recommended Therapies (SWEDEHEART) reported a benefit to revascularization in ACS in CKD patient groups with eGFR of 15 mL/min/1.73 m² or greater⁵⁹ ([Fig. 88-16](#)). Patients with more severe degrees of renal impairment and those on dialysis, although infrequently offered PCI, appeared to gain no improvement in survival with interventional management.

CARDIORENAL SYNDROMES

The term *cardiorenal syndrome* (see also [Chapters 24 and 25](#)) refers to disorders of the heart and kidneys whereby acute or chronic dysfunction in one organ may induce acute or chronic dysfunction in the other. Five distinct syndromes have been described according to the clinical scenario and time sequence of organ failure⁶⁰ ([Fig. 88-17](#)). The most common application of the designation cardiorenal syndrome is in patients with heart failure. The diagnosis of heart failure with concomitant renal failure presents a particular challenge. Patients with CKD, and in particular ESRD, have three key

mechanical contributors to heart failure: pressure overload (related to hypertension), volume overload, and cardiomyopathy ([Fig. 88-18](#)). Approximately 20% of patients approaching hemodialysis have pre-existing heart failure.⁶⁰ It is unclear how heart failure findings result from chronic volume overload from renal failure and how much from impaired systolic or diastolic function. CKD influences the blood levels of B-type natriuretic peptide (BNP) and NT-proBNP. In general, when the eGFR is less than 60 mL/min/1.73 m², higher cut points of 200 pg/mL and 1200 pg/mL should be used in the diagnosis of heart failure with BNP and NT-proBNP, respectively.^{61,62} Once acutely decompensated heart failure (ADHF) is recognized on clinical grounds, approximately 25% of patients will develop a cardiorenal syndrome during the hospitalization characterized by a rise in serum creatinine to 0.3 mg/dL or higher and a reduction in urine output. The RIFLE criteria identify three stages of acute kidney injury (risk, injury, failure) and two outcome measures (loss of renal function and ESRD). The magnitude of injury depends on the patient's rise in

Cardiorenal Syndrome (CRS) General Definition:

A pathophysiologic disorder of the heart and kidneys whereby acute or chronic dysfunction in one organ may induce acute or chronic dysfunction in the other organ

CRS Type I (Acute Cardiorenal Syndrome)

Abrupt worsening of cardiac function (e.g., acute cardiogenic shock or decompensated congestive heart failure) leading to acute kidney injury

CRS Type II (Chronic Cardiorenal Syndrome)

Chronic abnormalities in cardiac function (e.g., chronic congestive heart failure) causing progressive and permanent chronic kidney disease

CRS Type III (Acute Renocardiac Syndrome)

Abrupt worsening of renal function (e.g., acute kidney ischemia or glomerulonephritis) causing acute cardiac disorder (e.g., heart failure, arrhythmia, ischemia)

CRS Type IV (Chronic Renocardiac Syndrome)

Chronic kidney disease (e.g., chronic glomerular disease) contributing to decreased cardiac function, cardiac hypertrophy, and/or increased risk of adverse cardiovascular events

CRS Type V (Secondary Cardiorenal Syndrome)

Systemic condition (e.g., diabetes mellitus, sepsis) causing both cardiac and renal dysfunction

FIGURE 88-17 Definitions of cardiorenal syndromes. (Modified from Ronco C, Haapio M, House AA, et al: *Cardiorenal syndrome*. *J Am Coll Cardiol* 52:1527, 2008.)

FIGURE 88-16 Estimated hazard ratio for mortality at 1 year for patients treated either medically or with early revascularization. FIGURE 88-18 Pathophysiology of type 1 cardiorenal syndrome or worsening renal function after hospitalization for acutely decompensated heart failure. ADH = antidiuretic hormone; AF = atrial fibrillation; ANP/BNP = atrial natriuretic protein/B-type natriuretic protein; DM = diabetes mellitus; EPO = erythropoietin; HTN = hypertension; IL-18 = interleukin-18; KIM-1 = kidney injury molecule-1; LV = left ventricular; N-GAL = neutrophil gelatinase-associated lipocalin; NSAIDs = nonsteroidal anti-inflammatory drugs; NT-proBNP = N-terminal pro-B-type natriuretic peptide; OSAs = obstructive sleep apneas; RAS = renal artery stenosis; TNF = tumor necrosis factor; TZDs = thiazolidinediones; VSMC = vascular smooth muscle cell. (Modified from Herzog CA, Asinger RW, Berger AK, et al: Cardiovascular disease in chronic kidney disease. A clinical update from Kidney Disease: Improving Global Outcomes (KDIGO). *Kidney Int* 80:572, 2011.)

serum creatinine or reduction in eGFR, as well as the development of oliguria (<0.5 mL/kg/hr for 6 hours). Multiple studies have shown that the predictors of cardiorenal syndrome (type 1) include baseline eGFR, older age, female sex, increased baseline blood pressure, higher initial natriuretic peptide levels, and increased central venous pressure. That cardiorenal syndrome type 1 in patients with heart failure rarely occurs in the prehospital phase and more commonly develops after treatment is started in-hospital, implicates iatrogenic factors. The use of loop diuretics, probably by further activating the RAAS and possibly worsening intrarenal hemodynamics, is associated with cardiorenal syndrome type 1. In the Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness trial, the use of higher doses of loop diuretics resulted in a five-fold increased rate of worsening renal function.⁶³ Several randomized trials of diuretic strategies, use of renal-protective agents (rolophylline), intravenous natriuretic peptides, and neurohormonal antagonists have not prevented the development of cardiorenal syndrome in patients with ADHF.⁶⁴ Thus the acute management of ADHF in patients with impaired eGFR with conventional agents poses a particularly difficult challenge. An elevated serum creatinine is the most common reason for the use of positive inotropes or inodilators in hospitalized patients with heart failure. No published reports demonstrate favorable long-term outcomes from dobutamine infusion, which in the short term increases arrhythmias and mortality. Likewise, milrinone does not reduce mortality, but causes arrhythmias,

and requires dose adjustment for eGFR below 45 mL/min/1.73 m² (Table 88-6). Patients with advanced heart failure have reduced renal blood flow, decreased glomerular filtration rate, enhanced proximal reabsorption of water, increased absorption of sodium along the loop of Henle, and an overall reduced capacity of the nephron to excrete water. Furthermore, reduced effective arterial blood volume stimulates antidiuretic hormone release, which can worsen water retention. The clinical signs of this deterioration are an elevation in the serum creatinine and blood urea nitrogen, hyponatremia, edema, and excessive thirst.⁶⁵ Hyponatremia and excess body water are ameliorated slightly with oral tolvaptan or intravenous conivaptan; however, neither therapy reduces rehospitalization or mortality in this scenario. For a summary of available diuretics and their sites of action, see Chapter 25.

Observational studies and small trials using continuous venovenous ultrafiltration have shown short-term improvements in symptoms, reductions in fluid weight, shorter hospital stay, and reductions in rehospitalization. However, the Cardiorenal Rescue Study in Acute Decompensated Heart Failure (CARRESS-HF) in patients with persistent congestion and renal dysfunction found no clinical benefits of ultrafiltration over diuretic therapy, and more patients in the ultrafiltration group than in the pharmacologic therapy group experienced a serious adverse event (72% versus 57%; *P* = 0.03).⁶⁶ Until larger trials help define the indicated population, optimal timing, and mode of ultrafiltration and demonstrate longer-term reductions in

**TABLE 88-6 Selected Therapies for Heart Failure in Patients with Chronic Kidney Disease***

MEDICATION	NORMAL DOSE	DOSING CONSIDERATIONS IN CKD POPULATION	PHARMACOLOGY
Dobutamine	Acutely decompensated heart failure with low cardiac output: <i>Continuous infusion:</i> 5.0-15 µg/kg/min IV Initial rate 5.0 µg/kg/min IV, titrate to 5-20 µg/kg/min; no more than 40 µg/kg/min	No specific dose adjustments for patients with CKD Close monitoring for adverse effects, including arrhythmias, recommended Doses <5.0 µg/kg/min may produce hypotension	<i>Principal routes of metabolism:</i> methylation of the catechol and hepatic conjugation May increase renal clearance of other drugs in low cardiac output states
Milrinone	Acutely decompensated heart failure with low cardiac output: <i>Loading dose:</i> 50 µg/kg IV over 10 min; then: <i>Maintenance:</i> 0.375 to 0.75 µg/kg/min.	Recommended infusion rates by CrCl values (in mL/min/1.73 m ²) CrCl >50: no change CrCl 50: 0.43 µg/kg/min CrCl 40: 0.38 µg/kg/min CrCl 30: 0.33 µg/kg/min CrCl 20: 0.28 µg/kg/min CrCl 10: 0.23 µg/kg/min CrCl 5: 0.2 µg/kg/min	<i>Excretion:</i> unchanged in urine
Nesiritide	Acutely decompensated heart failure with pulmonary congestion: 2 µg/kg IV bolus over 1 minute, then 0.01 µg/kg/min IV infusion With hypotension, discontinue until patient is stabilized; then restart at 30% lower dose	No specific dose adjustments for patients with CKD Recommend close monitoring for adverse effects including hypotension	<i>Clearance mechanisms:</i> (1) binding to cell surface clearance receptors with subsequent cellular internalization and lysosomal proteolysis; (2) proteolytic cleavage of the peptide by endopeptidases, such as neutral endopeptidase, which are present on the vascular luminal surface; (3) renal filtration
Nitroprusside	Acutely decompensated heart failure with vasoconstriction: 0.25-0.8 µg/kg/min IV	No specific dose adjustments for patients with CKD Close monitoring for adverse effects, including hypotension and thiocyanate accumulation, recommended	Intraerythrocytic reaction, but hepatic and renal function affects thiocyanate accumulation
Hydralazine	Acute and chronic heart failure, in those intolerant to RAAS blockers: 25-50 mg by mouth 3× or 4×/day	Dose q8-16 h with CrCl <10 mL/min	<i>Clearance:</i> hepatic, 25%-40% removed with dialysis
Digoxin	Chronic systolic and diastolic heart failure, atrial fibrillation with rapid ventricular rate: 0.25 mg daily by mouth	0.125 mg by mouth once daily or every other day	<i>Excretion:</i> 50%-70% unchanged in the urine <i>Half-life:</i> prolonged in anuric patients (to 3.5 to 5 days) Digoxin: not effectively removed from the body by dialysis

IV = intravenous.

hospitalization and mortality, ultrafiltration represents a last-line approach for the patient with refractory cardiorenal syndrome.⁶⁷

The management of the patient who is already receiving dialysis and in heart failure requires particular care. In general, proven heart failure therapies, provided that they are tolerated, should be used along with regular and ad hoc dialysis as needed to control volume overload. In a randomized trial, carvedilol provided additional benefit in this scenario.⁶⁸ In addition, retrospective analyses supports the use of an ACE inhibitor or ARB (not the combination) in patients with ESRD with heart failure.⁶⁹

In summary, CKD and heart failure present a particularly challenging scenario for clinicians and patients. Frequent outpatient monitoring and avoidance of overly aggressive diuresis are advised. Dialysis patients, despite having volume reduction with mechanical fluid removal, should have medical therapy with ACE inhibitors or ARBs, beta blockers, and additional agents for blood pressure control if needed.

CHRONIC KIDNEY DISEASE AND VALVULAR HEART DISEASE

Impaired renal function may aggravate mitral annular calcification and aortic valve sclerosis.⁷⁰ Some 80% of patients with ESRD have the murmur of aortic sclerosis. Bacterial endocarditis may develop in patients with ESRD who have temporary dialysis access catheters.⁷¹ Endocarditis with common pathogens including *Staphylococcus*,

Streptococcus, and *Enterococcus*, in the mitral, aortic, or tricuspid valves, carries a risk of cerebral embolism of 40% and a mortality rate of 50% in ESRD.⁷¹ The combination of infective endocarditis and ESRD can be very difficult to treat on account of the continued need for dialysis access and the delay in surgical placement of permanent arteriovenous shunts or fistulas. Valve replacement in ESRD for endocarditis carries a very high mortality rate.⁷² In ESRD, tissue or mechanical valve prostheses demonstrate similar survival. The use of tissue valves can lessen the complicating issue of chronic anticoagulation and bleeding with repeated-dialysis vascular access.⁷³

RENAL FUNCTION AND ARRHYTHMIAS

Uremia, hyperkalemia, acidosis, and disorders of calcium-phosphorus balance all link to higher rates of atrial and ventricular arrhythmias. Concurrent left ventricular hypertrophy (LVH), left ventricular dilation, heart failure, and valvular disease all contribute to higher rates of virtually all arrhythmias in CKD, including bradyarrhythmias and atrioventricular block. Practical management concerns include dose adjustment for many antiarrhythmic medications including dofetilide and sotalol (**Table 88-7**). Observational studies suggest that patients with ESRD benefit from implantable cardioverter-defibrillators (ICDs) implantation for secondary prevention.^{74,75} Of concern, CKD, and ESRD in particular, may cause elevated defibrillation thresholds and failure of ICDs and lead to high rates of shock and antitachycardia pacing, warranting particularly close surveillance⁷⁴ (**Fig. 88-19**).

TABLE 88-7 Selected Antiarrhythmics in Patients with Chronic Kidney Disease

MEDICATION	NORMAL DOSE	DOSING CONSIDERATIONS IN CKD POPULATION	PHARMACOLOGY
Amiodarone	Acute ventricular and acute and chronic atrial arrhythmias: <i>First rapid:</i> 150 mg over 10 min (15 mg/min) <i>Followed by slow:</i> 360 mg over 6 hr (1 mg/min) <i>Maintenance infusion:</i> 540 mg over the remaining 18 hr (0.5 mg/min) Oral 800-1600 mg/day in divided doses until a total of 10 g has been given; then 200-400 mg/day	No specific dose adjustments for patients with CKD	<i>Metabolism/excretion:</i> primarily hepatic metabolism and biliary excretion; negligible renal excretion
Dronedarone	Atrial fibrillation/atrial flutter: 400 mg by mouth twice a day with morning and evening meals	No specific dose adjustments for patients with CKD	Dronedarone: extensively metabolized by the liver
Dofetilide	Atrial fibrillation/atrial flutter: <i>Initial dose:</i> 500 µg by mouth, twice daily QTc interval should be measured 2-3 hr after the initial dose; if QTc >15% of baseline, or if QTc >500 msec (550 msec in patients with ventricular conduction abnormalities), dofetilide dosage should be adjusted <i>Continued monitoring for doses 2-5:</i> QTc interval must be determined 2-3 hr after each subsequent dose of dofetilide for in-hospital doses 2-5; if measured QTc >500 msec (550 msec in patients with ventricular conduction abnormalities) dofetilide should be stopped	CrCl >60 mL/min: 500 µg bid CrCl 40-60 mL/min: 250 µg twice daily. CrCl 20-39 mL/min: 125 µg twice daily. CrCl <20 mL/min: Contraindicated	<i>Metabolism/excretion:</i> hepatic metabolism accounts for 20%-30%, 70%-80% renal elimination
Sotalol	Atrial fibrillation/atrial flutter: 80-160 mg orally twice a day	CrCl 30-59 mL/min: dosage interval should be increased to 24 hr CrCl 10-29 mL/min: dosage interval should be increased to 36 to 48 hr CrCl <10 mL/min: dose should be individualized	<i>Excretion:</i> unchanged in urine Removed with dialysis

IV = intravenous.

**FIGURE 88-19** Incidence of events in patients with implantable cardioverter-defibrillators with ESRD and those without. ATP = antitachycardia pacing. (Modified from Hreybe H, Ezzeddine R, Bedi M, et al: Renal insufficiency predicts the time to first appropriate defibrillator shock. *Am Heart J* 151:852, 2006.)

CONSULTATIVE APPROACH TO SEVERE KIDNEY DISEASE AND HEMODIALYSIS PATIENTS

The prevalence of angiographically significant coronary artery disease (CAD) ranges from 25% in young, nondiabetic hemodialysis patients up to 85% in older patients with ESRD who have long-standing diabetes mellitus.⁷⁶ The rate of cardiac death in dialysis patients younger than age 45 exceeds by 100-fold that in the general population. Medicare beneficiaries with CKD before initiation of dialysis are 60% more likely to have a billing claim submitted for the diagnosis of CVD and 70% more likely to have a claim submitted for

“atherosclerotic heart disease.”⁵⁶ Almost a third of diabetic renal transplant candidates have one or more lesions with greater than 75% stenosis.⁷⁷ Patients with ESRD have substantially more numerous, proximal, and severe coronary artery lesions, as well as more severe left ventricular dysfunction than those studied without CKD.⁵⁶ These patients have coronary heart disease death rates that are many-fold higher than those without ESRD, even with multiple cardiovascular risk factors (Fig. 88-20).

Hypertension affects 80% of patients with ESRD, and only 30% achieve adequate control.⁷⁸ Long-term cardiorenal protection involves two important concepts: blood pressure control to a much lower target of a systolic blood pressure less than 130 mm Hg, and use of an agent that blocks the RAAS, such as an ACE inhibitor or ARB, as the base of therapy. RAAS interruption can benefit even anephric patients, because ACE inhibitors/ARBs can reduce LVH and possibly improve survival.⁷⁹ A retrospective study found that although only approximately 20% of patients with ESRD and CVD receive ACE inhibitors, those who did after CAD events showed improved all-cause mortality over the next 5 years.⁷⁹ Adjusting the dialytic regimen can help manage ACE inhibitor/ARB-related hyperkalemia in patients with ESRD.

Beyond a base of ACE inhibitor and/or ARB, beta blockers can serve as both antihypertensive and anti-ischemic agents. In patients with heart failure, beta blockers improve left ventricular ejection fraction and reduce rates of hospitalization, sudden death, and all-cause mortality.⁷⁹ Patients with ESRD who receive beta blockers after CAD events have large relative risk reductions in all-cause mortality.⁵⁶

Additional choices of antihypertensive or cardioprotective agents should be based on ease of management, compliance, and lack of adverse effects. The goal is to create a blood pressure environment for the cardiovascular system in which the mean systolic blood pressure on 24-hour monitoring is no higher than 130 mm Hg. Guidelines for patients without ESRD state that the optimal office systolic blood pressure should be below 130 mm Hg. The difficult task in the patient

FIGURE 88-20 Risk of coronary heart disease death by gradations of CKD and diabetes. CKD = chronic kidney disease; DM = diabetes mellitus; USRDS = US Renal Data Systems. (Modified from Levin A, Stevens L, McCullough PA: Cardiovascular disease and the kidney. Tracking a killer in chronic kidney disease. *Postgrad Med* 111:53, 2002.)

with ESRD is to achieve these goals without inducing hypotension during dialysis sessions. In view of the high rates of severe CAD in ESRD, hypotension during dialysis can worsen clinical and subclinical ischemia recognized as chest discomfort, shortness of breath, ST-segment depression on electrocardiography, and elevations of cTn on blood testing.

The goal of low-density lipoprotein (LDL) cholesterol reduction, in most cases with a statin and ezetimibe, in patients with ESRD is supported by a 17% reduction in major atherosclerotic events shown in the Study of Heart and Renal Protection in patients with predialysis CKD and ESRD.⁸⁰ In addition, agents that reduce triglycerides and raise high-density lipoprotein (HDL) cholesterol including nicotinic acid and fibrates can be used according to the National Cholesterol Education Project Adult Treatment Panel III (NCEP-ATP-III) Guidelines. Niacin has the additional benefit of modestly lowering phosphate in ESRD. Colesevelam, a bile acid sequestrant, also can aid in lowering serum phosphorus.

In ESRD associated with diabetes mellitus, blood glucose control to a target glycohemoglobin below 7 mg/dL can be expected to reduce rates of microvascular complications (retinopathy) and, to a lesser extent, clinically important atherosclerotic disease elsewhere (AMI, stroke, CVD-related death).⁵⁶ Likewise, smoking cessation as another basic reduction maneuver is recommended in patients with ESRD.⁵⁶ Unlike with the preventive effects seen in the general population for patients after AMI, chronic administration of antiplatelet agents (aspirin and clopidogrel) as well as warfarin has been associated with increased risk of death in patients with incident ESRD even when these effects are controlled for background conditions.⁸¹ Thus the specific use of antiplatelet or antithrombotic agents for the prevention of CVD risk in ESRD should be undertaken with caution.

In the setting of stable symptomatic CAD, an analysis from the Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial suggested PCI had no benefit over optimal medical therapy in patients with predialysis CKD.⁸² No similar trial data are available for patients with ESRD. After treatment with optimal medical therapy in a patient with ESRD and symptomatic CAD, the next step is coronary angiography and consideration of revascularization. In the common scenario of multivessel disease, multiple studies have shown that outcomes after coronary artery bypass grafting (CABG) are superior to those achieved with PCI with drug-eluting stents.⁸³ It is widely accepted that patients with ESRD undergoing mechanical coronary revascularization procedures are at increased risk for adverse events including death. Dialysis-dependent patients undergoing CABG face a 4.4-fold increased risk of in-hospital death, a 3.1 times greater risk of mediastinitis, and a 2.6-fold increased risk of stroke compared with those patients undergoing CABG who were not on dialysis.⁵⁶

In summary, patients with ESRD have more than CAD risk equivalent status in their baseline CAD risk assessment. An aggressive approach with medical management for CAD is warranted, even in the case of subclinical CAD. A low threshold for diagnostic testing is appropriate in patients with ESRD. When significant multivessel CAD is found, patients with ESRD appear to benefit more from revascularization with CABG than with PCI, and if this approach is clinically reasonable, they should be given that opportunity for improved survival and reduction in future cardiac events.

EVALUATION AND MANAGEMENT OF THE RENAL TRANSPLANT RECIPIENT

Cardiovascular screening is recommended in high-risk CKD patients before renal transplantation.⁸⁴ These include persons with diabetes mellitus, men over age 45 years, women older than 55 years of age, previous history of ischemic heart disease, an abnormal electrocardiogram, left ventricular dysfunction, smoking history, and duration of dialysis more than 2 years. Controversies exist regarding the ideal screening test for CAD in patients with ESRD. The choice of exercise versus pharmacologic stress and echocardiographic versus nuclear scintigraphic imaging must be individualized. A suggested algorithm proposed by Stenvinkel and Herzog featuring dobutamine stress echocardiography is shown in [Figure 88-21](#). Lentine and colleagues in 2008 analyzed the United States Renal Data System in 27,786 eligible patients for renal transplantation and concluded that 46.3% of patients underwent cardiac evaluation before transplantation, of whom 9.5% required coronary revascularization. Among patients who underwent transplantation without cardiovascular evaluation, the 3-year incidence of posttransplantation AMI was 3% in lower-risk group and 10% in higher-risk group based in clinical features.⁸⁵ Coronary angiography and revascularization can be performed with very little loss in renal function in very-low-eGFR groups if done carefully with staged intervals between the diagnostic procedure and PCI or CABG, as shown by Kumar and co-workers⁸⁶ ([Fig. 88-22](#)).

SUMMARY

Recognition has increased over the past decade that patients with CKD are at high risk for development of CVD. Common clinical scenarios in which renal function influences care include PCI, cardiac surgery, ACS, heart failure, valvular disease, and arrhythmias. Results from retrospective studies and clinical trial subgroups form the basis of current recommendations, given the lack of prospective randomized trials in CKD and ESRD. Further study of the adverse

Cardiovascular function is closely linked and responsive to numerous endogenous and exogenous factors. This interplay is mediated through rapid and often subtle neurohormonal changes. One of the most important mechanisms whereby rapid circulatory control is achieved is the autonomic nervous system, which modulates cardiac function through direct effects on the heart and vascular tone.

OVERVIEW OF NEURAL CIRCULATORY CONTROL

The autonomic nervous system can be subdivided into sympathetic, parasympathetic, and enteric components. The principal cardiovascular influences are mediated through the sympathetic and parasympathetic systems. The interplay between these two systems and their relative balance help determine cardiovascular responses under a variety of conditions. These responses usually take the form of changes in blood pressure (BP) or heart rate. Knowledge of the physiology whereby BP and heart rate react to autonomic modulation is important for understanding how disorders of the autonomic nervous system can affect cardiovascular function.

Baroreceptors

Autonomic responses, capillary shift mechanisms, hormonal responses, and kidney and fluid balance mechanisms all interact to maintain control of BP. Of these, the autonomic nervous system offers the most rapid response system. Neural circulatory regulation occurs via increased contractility of the heart or vasoconstriction of the arterial or venous circulations in response to information received from baroreceptors. This afferent information is synthesized and integrated and appropriate responses generated in the vasomotor center of the brain.

The reflexes by which BP is maintained are collectively known as the baroreflex, which includes arterial baroreceptors (also known as the high-pressure receptors) and cardiopulmonary receptors (the low-pressure receptors). Under normal physiologic circumstances, sympathetic activity is inhibited and parasympathetic activity predominates.

Arterial Baroreceptors

Arterial baroreceptors are located in the carotid sinuses, in the aortic arch, and at the origin of the right subclavian artery. The carotid sinus baroreceptors are innervated by the glossopharyngeal nerve (cranial nerve IX), and the aortic arch baroreceptors are innervated by the vagus nerve (cranial nerve X). Baroreceptors are stretch-dependent mechanoreceptors that sense changes in pressure, which is transmitted via afferents to the nucleus tractus solitarius (NTS) in the brainstem. When distended, the baroreceptors are activated and generate action potentials that increase in frequency in correlation to the amount of stretch. Thus spike frequency is used as a surrogate measure of BP at the level of the NTS, with higher frequency correlating with higher BP.

The arterial baroreceptors are tonically active under normal circumstances at a mean arterial pressure (MAP) higher than 70 mm Hg, which is termed the baroreceptor set point. With MAPs below the set point, the baroreceptors become essentially silent. However, the set point may vary with persistent changes in BP, such as in chronic hypertension, in which the set point is increased, or in chronic hypotension, in which it is decreased (see Chapter 43). The set point may vary, depending on other endogenous factors and disease states.

Integration of baroreceptor afferent signals is achieved at the level of the NTS. The NTS sends inhibitory fibers to the vasomotor center, which regulates the sympathetic nervous system, and excitatory fibers to vagal nuclei that regulate the parasympathetic system. Activation of the NTS (associated with increased action potential frequency from arterial baroreceptors) stimulates parasympathetic outflow, whereas an inactive nucleus induces sympathetic activation and parasympathetic inhibition. Sympathetic activation leads to increased cardiac contractility, increased heart rate, venoconstriction, and arterial vasoconstriction, which ultimately results in increased BP via elevation of total peripheral resistance and cardiac output. Parasympathetic activation leads to a decrease in heart rate and a minor decrease in contractility, thereby resulting in a decrease in BP.

*The author is grateful to Drs. Rose Marie Robertson, David Robertson, and Suraj Kapa for contributions to previous editions of this chapter.

Coupling of sympathetic inhibition with parasympathetic activation allows the baroreflex to maximize the reduction in BP. Conversely, sympathetic activation with parasympathetic inhibition allows an increase in BP.

Cardiopulmonary Baroreceptors

Although arterial baroreceptors are the most sensitive receptors, low-pressure receptors in the heart and venae cavae termed cardiopulmonary receptors also play a role in modulation of BP. They respond primarily to changes in volume but also to chemical stimuli. They project via vagal afferents to the NTS and via spinal sympathetic afferents to the spinal cord. Stimulation results in vasodilation and inhibition of vasopressin release. Furthermore, a stretch stimulus depresses renal sympathetic nerve activity and has been shown to play a role in modulating renin release, thereby resulting in diuresis and natriuresis and thus regulating whole-body fluid volume to maintain BP homeostasis.¹ The cardiopulmonary receptors have only limited direct influence on control of the heart rate.

Heart Rate Modulation

Under normal circumstances, the intrinsic sinus nodal rate is 95 to 110 beats/min at rest, but efferent parasympathetic input via the vagus nerve suppresses the sinus nodal rate to 60 to 70 beats/min. During rest there is little sympathetic efferent input and a low concentration of catecholamines. This changes with any movement away from the resting state, such as with physical exertion, during which sympathetic activity increases and parasympathetic activity decreases. On termination of exertion, recovery of the resting heart rate is again governed largely by parasympathetic dominance.

Although cardiac automaticity is intrinsic to pacemaker activity (see Chapter 33), the autonomic nervous system plays a primary role under normal conditions in defining the heart rate and rhythm. The parasympathetic influence is achieved via release of acetylcholine from the vagus nerve, which increases conductance of potassium across the cell membrane. In addition, acetylcholine inhibits the hyperpolarization-activated pacemaker current. This effect is quickly dispersed because of the high acetylcholinesterase concentration around the sinus node. The sympathetic influence is achieved by release of epinephrine and norepinephrine, which causes cyclic adenosine monophosphate-mediated phosphorylation of membrane proteins and a resultant increase in the inward calcium current and accelerated slow diastolic depolarization. In addition, other endogenous factors, such as nitric oxide, influence channel function and further modulate autonomic control of the heart rate.

Breathing and Chemoreflexes

The chemoreflexes are modulators of sympathetic activation and play an important role in cardiovascular autonomic tone. The chemoreceptors are most simply divided into their central and peripheral components. Peripheral chemoreceptors are located in the carotid bodies and respond to hypoxemia, whereas central chemoreceptors are located in the brainstem and respond mostly to hypercapnia. Hypoxemia or hypercapnia results in hyperventilation and vascular sympathetic activation. Inhibitory influences on the chemoreflex drive are seen with stretch of the pulmonary afferents and with activation of the baroreflex, both of which have a greater influence on peripheral than on central chemoreflexes.

In numerous clinical conditions there is a substantial role of chemoreflexes in the modulation of neural circulatory control. One is sleep apnea (see Chapter 75), in which the sympathetic vasoconstrictor response to hypoxia is potentiated because of elimination of the inhibitory influence on chemoreflexes by stretch of the pulmonary afferents. Another is early hypertension, in which the ventilatory response to hypoxemia is increased, in addition to an increase in sympathetic tone. This may be caused in part by impaired baroreflex sensitivity in hypertensive patients, as well as by an increased chemoreflex drive. The tonic chemoreflex drive in patients with obstructive sleep apnea (OSA) can be reversed by the use of 100% oxygen, which reduces the heart rate, BP, and sympathetic outflow. Administering 100% oxygen to patients with borderline hypertension and to spontaneously hypertensive rats also reduces not only ventilation but vasoconstrictor tone as well.

Diving Reflex

Under circumstances of prolonged apnea, a unique state of simultaneous increased parasympathetic drive to the heart and increased sympathetic drive to the vasculature occurs (Fig. 89-1). This state is seen in diving mammals and sometimes in humans during prolonged submersion in water. In response to hypoxia, the body usually seeks to increase ventilation and blood flow to end organs to maintain tissue oxygenation. However, in response to prolonged hypoxia in the absence of breathing, the body no longer experiences replenishment of oxygen stores and the normal homeostatic mechanisms alter to maintain oxygen delivery to organs vital to life—the brain and heart. This is achieved by decreasing oxygen delivery to much of the rest of the body via increased sympathetic vasoconstriction. This increased sympathetic outflow, however, does not constrict the cerebral vasculature because cerebral vascular tone is under autoregulatory control. Furthermore, myocardial oxygen demand is decreased because of bradycardia caused by an increase in parasympathetic tone. Thus, it is possible for individuals under exceptional circumstances to survive for prolonged periods of up to 5 minutes or longer under anoxic conditions.

FIGURE 89-1 Components of the diving reflex. Shown are recordings of intraarterial BP, central venous pressure (CVP), electrocardiogram (ECG), sympathetic nerve activity (SNA), and respiration (RESP) during apnea lasting 30 seconds. SNA is reflected by the frequency and amplitude of bursts. Toward the end of the apneic period, increases in BP, CVP, and SNA are noted, in addition to progressive bradycardia with eventual complete heart block. Furthermore, O₂ saturation fell to 92%. With release of apnea, the ECG and SNA changes resolve, with some temporarily continued elevation in BP. (From Somers VK, Dyken ME, Mark AL, Abboud FM: Parasympathetic hyperresponsiveness and bradyarrhythmias during apnoea in hypertension. *Clin Auton Res* 2:171, 1992.)

AUTONOMIC TESTING

Experimental evidence of an association between lethal arrhythmias and increased sympathetic or reduced vagal activity has spurred the development of several quantitative markers of autonomic activity. Generally, the two easiest and most economic means of studying the interplay between autonomic and cardiac function are via orthostatics and the Valsalva maneuver, although both are nonspecific. When a patient is evaluated for syncope, a cost-effective means of exploring a neurocardiogenic cause is with a tilt-table test (see Chapters 34 and 40). Furthermore, studies of baroreflex sensitivity, heart rate variability, heart rate recovery, and chemoreflexes have been shown to be of assistance in direct assessment of autonomic dysfunction. Finally, blood levels of norepinephrine and its metabolites may assist in discriminating between different types of dysautonomia.

Orthostatics

Orthostatic hypotension (OH) is defined as a decrease of more than 20 mm Hg in systolic pressure or a decrease of more than 10 mm Hg in diastolic pressure after rising to a standing position from a supine position. BP and heart rate should be measured after symptoms develop or once 3 minutes has passed after rising to the standing position. If the patient is unable to stand, orthostatics may be done after the patient has risen to a sitting position with the feet dangling over the edge of the bed. OH is an inability to maintain sufficient BP and adequate cerebral perfusion against gravity. Generally, on arising from a supine position, an average person may lose about 700 mL of blood from the thorax. This results in decreased stroke volume, as well as decreased systolic pressure and increased diastolic pressure. Compensation occurs via an increase in heart rate and slight peripheral vasoconstriction. In individuals intolerant of orthostasis, venous pooling secondary to decreased muscle and vascular tone and decreased circulating blood volume may develop in response to standing. When testing orthostatics it is important to note that a significant decrease in BP without a corresponding rise in heart rate suggests abnormal autonomic innervation to the heart and may represent an underlying neuropathy, chronotropic incompetence, or drug therapy that blunts the heart rate response, such as beta blockade.

Valsalva Maneuver

The Valsalva maneuver becomes useful for testing patients at the bedside when done in conjunction with continuous electrocardiographic monitoring. During monitoring the patient blows continuously into a closed system for 12 seconds at 40 mm Hg, and the fastest heart rate during the maneuver is divided by the slowest heart rate immediately afterward. A quotient of less than 1.4 is suggestive of autonomic impairment. However, this is nonspecific. Recovery of BP after the Valsalva maneuver may provide a useful measure of adrenergic vasoconstrictor reserve (see later). The systolic BP (SBP) response to the Valsalva maneuver has four phases. Phase 1 apparently increases BP with onset of the Valsalva maneuver, and phase 2 represents normalization of BP during a sustained Valsalva maneuver. Phase 3 represents a dip after Valsalva release, and Phase 4 involves an "overshoot" several seconds later. In patients with pulmonary hypertension, a prompt fall in SBP during phase 2 suggests normal pulmonary artery wedge pressure, whereas sustained elevation denotes left-sided congestion, thus providing noninvasive insight into the hemodynamic basis of pulmonary hypertension.² Measurement of left ventricular outflow tract obstruction via the Valsalva maneuver has been proposed as a reliable means of evaluating the indication for percutaneous transluminal septal myocardial ablation, as well as for assessment of treatment effect.³ A "sympathetic index" derived from the change in BP at baseline and the level during phase 2 has been suggested as a useful sign of OH and sympathetic failure (see later).⁴

Other Tests of Autonomic Function Baroreflex Sensitivity

Testing baroreflex control of the heart rate involves measuring the reflex increase in the R-R interval in response to an increase in BP. The increase in BP has historically been achieved by use of an

alpha-adrenergic agonist, most often phenylephrine. Intravenous injection of a bolus of phenylephrine induces a 20- to 30-mm Hg increase in SBP. Generally, a linear relationship exists between the increase in the R-R interval and the increase in SBP. The slope is used to quantify the sensitivity of the arterial baroreflex; it is typically steep in healthy individuals but decreases with advancing age and flattens even more with severe cardiovascular disease, such as hypertension or heart failure.

As a measure of autonomic function, baroreflex sensitivity decreases (i.e., shows a flatter slope) with sympathetic dominance and increases (i.e., shows a steeper slope) with parasympathetic dominance. In the search for noninvasive ways to measure baroreflex sensitivity, various devices and maneuvers have been used. The FINA-PRES (from finger arterial pressure) device is one such example and has been used in the ATRAMI (Autonomic Tone and Reflexes After Myocardial Infarction) study. Spontaneous increases and decreases in BP, as well as associated changes in the R-R interval, have been used to determine the spontaneous baroreflex. Furthermore, spectral techniques for analyzing the relationship between beat-to-beat oscillations in BP and R-R intervals are being studied as possible alternatives to the more invasive method of phenylephrine infusion.

Generally, autonomic testing evaluates the baroreflex by measuring changes in heart rate in response to increases and decreases in BP. However, the baroreflex regulates BP by changing not only the heart rate (vagal component) but also peripheral resistance (adrenergic component). A potentially useful nuance in baroreflex testing has been the differentiation between adrenergic and vagal baroreflex sensitivity.⁵ Adrenergic baroreflex sensitivity relates the BP recovery time to the preceding decrease in BP induced by the Valsalva maneuver, in a sense measuring the sympathetic vasoconstrictor response to hypotension. This may provide a helpful index for evaluating and monitoring patients with adrenergic failure.

Chemoreflexes. Studies of chemoreflex function are one way of determining the dominant respiratory response, as well as breathing-heart rate-BP interactions, in certain diseases. As noted, the hypercapnic response is mediated mainly by central chemoreceptors, whereas the hypoxemic response is mediated by peripheral chemoreceptors.

Heart Rate Variability

Heart rate variability has become a commonly used but difficult-to-interpret means of studying the interplay between the autonomic nervous system and cardiovascular function. The phenomenon being measured in heart rate variability is oscillation in the interval between consecutive heartbeats, as well as the variance in heart rates.

Actual measurement of heart rate variability has been achieved via multiple different modalities, most notably by using time domain and frequency domain methods. It is usually calculated by analyzing the time series of beat-to-beat intervals from electrocardiographic or arterial pressure tracings. A simple example of time domain measurement of heart rate variability is calculation of the standard deviation of beat-to-beat intervals. The time domain graph of a value shows how the signal varies over time. The frequency domain graph, however, shows how much of a signal lies within given frequency bands over a range of frequencies. It involves the use of mathematical transforms, such as the Fourier transform, to decompose a function into an infinite or finite number of frequencies. Spectral density analysis is the most common frequency domain method used and involves measurement of how the power of a signal or time series is distributed at any particular frequency.

A common frequency domain method involves application of the discrete Fourier transform to the beat-to-beat interval time series. The frequency bands of most interest in humans are the high-frequency (HF) band, low-frequency (LF) band, very low-frequency (VLF) band, and ultralow-frequency (ULF) band, each of which has its own physiologic correlate. The HF band lies between 0.15 and 0.4 Hz and is driven by respiration; it appears to derive mainly from vagal activity. The LF band, which lies between 0.04 and 0.15 Hz, appears to derive from vagal and sympathetic activity and is believed to reflect delay in the baroreceptor loop. The VLF band lies between 0.0033 and 0.04 Hz and has been attributed to physical activity. Finally, the ULF band lies between 0 and 0.0033 Hz and is associated with day-night variation.

Other means of calculating heart rate variability include phase domain measurement and other nonlinear dynamic methods. The information provided by each measuring method, however, is complementary and should be taken together to define and understand the characteristics of heart rate variability in a given disorder.

The usefulness of heart rate variability as a measure of autonomic function and as a predictor of mortality has been suggested by a number of studies. In the 1970s, Wolf and colleagues showed a higher risk for postinfarction mortality with reduced heart rate variability, and Ewing and associates developed simple bedside tests that use short-term differences in the R-R interval as a means of detecting autonomic neuropathy in diabetics. In the late 1980s, heart rate variability was shown to be an independent predictor of post-myocardial infarction mortality. Altered heart rate variability has been associated with other pathologic conditions such as hypertension, hemorrhagic shock, and septic shock and has been accepted as an independent predictor of mortality after myocardial infarction.⁶

Heart rate turbulence, thought to be a reflection of baroreflex sensitivity, may also provide prognostically useful information. Abnormal heart rate turbulence has been linked to total mortality and sudden death in patients after myocardial infarction and those with heart failure⁷ and may be useful in predicting arrhythmic risk in heart failure patients with a left ventricular ejection fraction higher than 30%.⁸ In diabetes, abnormal heart rate variability can be used to help identify cardiovascular autonomic neuropathy (see later), which is also accompanied by increased risk for mortality.⁹ Sudden death is the major cause of cardiac mortality in patients with end-stage renal disease (ESRD). Emerging evidence suggests that impairments in heart rate variability and baroreflex function may help identify patients with ESRD at greatest cardiac risk.¹⁰

Heart Rate Recovery

During exercise the heart rate rises, initially secondary to a reduction in vagal tone and then because of increased sympathetic activity. After exercise, parasympathetic reactivation and reduced sympathetic activity contribute to the recovery of resting heart rate. The rate at which the heart rate returns to baseline, measured over the first minute after exercise, is termed heart rate recovery. Delayed heart rate recovery is a marker of decreased vagal activity, which has been shown to be an independent risk factor for sudden cardiac death.¹¹ Patients with heart failure and a preserved ejection fraction, in contrast to hypertensive and healthy controls, have impaired heart rate recovery, as well as chronotropic incompetence during maximal exercise.¹² Postexercise heart rate recovery may also be a useful tool in screening for cardiac autonomic neuropathy in patients with type 2 diabetes (see later).¹³

Tilt-Table Testing

Tilt-table testing is often conducted in patients with a history of syncope to diagnose possible dysautonomic causes of syncope (see [Chapter 40](#)). The test is considered positive if the patient experiences symptoms associated with a drop in BP or an arrhythmia. These abnormalities are suggestive of dysfunction of the autonomic system. Normally, BP will compensate via an increase in heart rate and constriction of blood vessels in the legs. In some patients, fainting or syncope could be associated with a precipitous drop in BP (vasodepressor syncope) or pulse rate (cardioinhibitory syncope) or a mixed response, thus requiring continuous monitoring of both.

Orthostatic Hypotension

OH (not the same as orthostatic intolerance; see later) is secondary to neurogenic and non-neurogenic conditions.¹⁴ Neurogenic causes are addressed later (see [Autonomic Dysregulation](#)). Non-neurogenic causes include hypovolemia, cardiac dysfunction, and medications (including those used to treat hypertension, myocardial ischemia, depression, psychosis, and Alzheimer and Parkinson disease). OH and tachycardia may also occur after prolonged bed rest or following exposure to microgravity, such as in space flight. In some patients, OH may be accompanied by fatigue, cognitive dysfunction, and emotional difficulties, as well as by abnormalities in gait and falls.^{15,16}

Symptoms can be debilitating and confine patients to bed; the consequent physical deconditioning may worsen the overall problem. Longitudinal studies have suggested that OH can increase the risk for stroke, myocardial ischemia, and mortality (see later). The therapeutic goal is to attenuate or eliminate symptoms rather than restore normotension. Pharmacologic therapy is often suboptimal and should be combined with interventions such as compression of venous capacitance beds, use of physical countermeasures, and intermittent water bolus treatment. Treatment can be difficult, and the development of supine hypertension should be minimized, especially in patients with diabetes, heart failure, or cardiac ischemia.

However, although symptoms of OH may include dizziness and syncope, asymptomatic OH is far more common and represents an independent risk factor for mortality and cardiovascular disease.¹⁵ In a prospective study of more than 33,000 individuals, OH was present in over 6% and was associated with age, female sex, hypertension, antihypertension treatment, increased heart rate, diabetes, low body mass index, and recurrent smoking.¹⁶ Those with OH had significantly greater risk for all-cause mortality, especially those younger than 42 years, and higher risk for coronary events.¹⁶

AUTONOMIC DYSREGULATION

Dysautonomias refer to any dysfunction of the autonomic nervous system, whether central, peripheral, or secondary to other disease processes. In general, the most common dysautonomias are those affecting the sympathetic system. However, the parasympathetic system and conditions of increased parasympathetic tone, such as during sleep or with endurance training, are also important to understand because they can have significant implications for cardiovascular health.

The sympathetic dysautonomias are the most common and may be characterized by disorders of release, function, or reuptake of norepinephrine, the main sympathetic chemical messenger. Furthermore, altered local blood flow and clearance of norepinephrine from the circulation can be manifested as a dysautonomia. The sympathetic dysautonomias can generally be divided into two groups—those associated with decreased function, in which orthostasis often occurs, and those associated with increased outflow, in which hypertension and/or tachycardia may be present.

Primary Chronic Autonomic Failure

Orthostatic intolerance is a key manifestation of neurocirculatory failure. It often serves as the initial symptom. However, not all OH is symptomatic of neurocirculatory failure. Most cases of OH result from blood loss, volume depletion, or a prolonged bedridden state. Only rarely does it result from true autonomic failure.

Chronic autonomic failure is distinguishable from acute-onset autonomic dysfunction syndromes by its progressive nature and prognosis. Generally, chronic autonomic failure can be subdivided into secondary and primary failure, with secondary failure being far more common. In cases of secondary failure, the cause is usually clear and treatment involves therapy for the underlying disorder. However, when autonomic failure dominates the clinical findings and a clear cause is not apparent, it is termed *primary chronic autonomic failure*.¹

Primary autonomic failure may be subdivided into three major syndromes—pure autonomic failure, multisystem atrophy (MSA), and Parkinson disease (PD). Major overlap among these three syndromes exists, and treatment differs between them.

Pure Autonomic Failure

Pure autonomic failure involves OH in the absence of symptoms or signs of central neurodegeneration. Thus the dysfunction occurs at the level of peripheral neurons and not in the central nervous system. The functional error lies in available levels of norepinephrine, which are low when supine and rise minimally with standing.¹ OH and an inadequate chronotropic response to standing and to the Valsalva maneuver are therefore evident. No direct effect on longevity occurs in these patients.

Multisystem Atrophy

MSA includes autonomic failure with signs and symptoms of progressive central neurodegeneration. It is generally divided into parkinsonian, cerebellar, and mixed forms. Symptoms develop in the sixth or seventh decade of life, and patients exhibit sympathetic and parasympathetic dysfunction. In addition to OH, findings may include impotence, loss of sweating, abnormal pupillary responses, reduced intraocular pressure, and urinary incontinence. Alveolar hypoventilation, central sleep apnea, and other breathing abnormalities may be present. However, in a study of patients with MSA, ventilatory responses to hypoxia and hypercapnia during wakefulness were preserved despite the presence of autonomic failure and impaired cardiovascular responses to these stimuli.¹⁷ Patients with MSA are known to have neuropathologic evidence of neurodegeneration in putative chemosensitive areas,¹⁸ thus suggesting that a critical number of chemosensitive neurons need to be lost before respiratory responses during wakefulness are overtly impaired. Urine production is greater in these patients during the night, which leaves them more hypovolemic in the morning and exaggerates the symptoms further.

Orthostatic changes may be striking, with as much as a 100-mm Hg fall in SBP on standing and a minimal rise in heart rate. Because of the progressive nature and the chronicity, patients may tolerate this precipitous drop in BP relatively well. However, in some patients, secondary orthostatic angina, which is actually exacerbated by the use of nitroglycerin, may occur. Patients often exhibit hypertension when supine, thus suggesting an inappropriate level of circulating catecholamines. In actuality, however, plasma levels of catecholamines and their metabolites are preserved, but not appropriately elevated on standing.

Life span in patients with MSA is diminished, and such patients live on average 9 years after diagnosis. Movement abnormalities are centrally mediated and do not often respond to pharmacologic intervention. Furthermore, respiratory compromise can occur progressively along with the development of nocturnal stridor, which may require continuous positive airway pressure.¹

Parkinson Disease with Autonomic Failure

This entity is similar in clinical appearance to MSA with parkinsonian features. The most common cause of PD is diffuse disease of autonomic centers in the brain, which results in autonomic dysfunction similar to that described earlier, and organs are affected diffusely.

Diagnosis and Therapy

Distinguishing pure autonomic failure from MSA and from PD with autonomic failure tends to be easier than distinguishing between the latter two. Magnetic resonance imaging (MRI) of the brain in pure autonomic failure will not reveal any central nervous system abnormalities, whereas in the other two it will demonstrate central lesions. Differentiating between MSA and PD is important because the prognosis in MSA is much worse. In MSA, consistent with a preganglionic lesion, norepinephrine transport is usually preserved. Uptake is impaired in PD, thus suggesting cardiac sympathetic denervation.¹⁹ Growth hormone responses to clonidine or to arginine are also impaired in MSA, but in PD growth hormone increases after clonidine and responds normally to arginine.¹⁹

Neuroimaging techniques have also been used to distinguish the three types of autonomic failure. Cardiac sympathetic nerves take up 123I-metaiodobenzylguanidine (123I-MIBG) and 6-(18F)-fluorodopamine, postganglionic adrenergic markers that radiolabel vesicles in the sympathetic nerve terminals and thereby allow visualization of cardiac innervation. In patients with MSA, normal uptake and hence intact cardiac sympathetic innervation are noted. However, patients with PD or pure autonomic failure show no detectable activity in the myocardium on emission scans, consistent with loss of sympathetic innervation of the heart. Thus, even though PD with autonomic failure may demonstrate central lesions, there is a suggestion of an additional postganglionic lesion in these patients that is distinct from the isolated preganglionic lesion of MSA.

The second consensus statement for the diagnosis of MSA reflects the advances and challenges in this field.²⁰ Autonomic defects may be more strikingly abnormal in MSA than in PD.²¹ These differences

were sustained and greater at 1-year follow-up, which suggests a more rapid progression of dysautonomia in MSA than in PD. These findings further support the concept that the primary lesion in MSA is preganglionic and in PD is ganglionic and postganglionic.

Therapy depends on changes in lifestyle in addition to pharmacologic therapy. Ingestion of carbohydrates can lower BP, and a meal before bedtime may be helpful in reducing nighttime supine hypertension. This depressor effect can be difficult for patients after meals during the day, so caffeine ingestion or the use of somatostatin in the case of severe decreases in BP can be used to attenuate the hemodynamic response to food. Furthermore, water intake can help increase BP. Physical maneuvers that cause compression of the lower extremities have also been noted to help patients symptomatically.¹

Pharmacologically, the two main areas of intervention include volume expansion and pressor administration. Use of fludrocortisone and adding sodium to the diet can help in expanding volume. The use of pressor agents should be considered in the context of the postganglionic or preganglionic nature of the different diseases. In patients with sympathetic cardiac denervation (i.e., pure autonomic failure or PD with autonomic failure), midodrine (an alpha-adrenoreceptor agonist) or L-threo-3,4-dihydroxyphenylserine (a norepinephrine precursor converted by parenchymal cells) may be useful. However, patients with MSA in whom sympathetic innervation is intact may benefit from the use of a sympathomimetic amine or alpha2-adrenoreceptor blocker. Also, ma huang or yohimbine may be useful because they induce release of norepinephrine from the sympathetic nerve terminal, but they could cause acute hypertension if used improperly.¹

Secondary Autonomic Failure

More commonly, autonomic failure occurs in the context of some other disease process, and treatment of the underlying process may or may not relieve the autonomic dysfunction. The most common cause of secondary autonomic failure is diabetes (see Chapter 61). Diabetic neuropathy is a well-known, long-term complication, and all nerves may be affected, both somatic and autonomic. Even in patients with impaired glucose tolerance, cardiovascular autonomic neuropathy may be evident, especially in men with central obesity.²² Cardiovascular complications secondary to dysfunction of autonomic control have been described in diabetic patients with and without OH. Heart rate variability and baroreflex testing may help in the detection of diabetic autonomic neuropathy. Nerve conduction abnormalities may not be the only component of autonomic dysfunction in diabetes. Relationships between vascular stiffness and dysfunction of the baroreflex have also been noted. Furthermore, some studies have suggested that the primary dysfunction may be defective activation of central parasympathetic pathways. Thus, there appear to be afferent and efferent, as well as sympathetic and parasympathetic, components.

Glucose and BP control may protect against neuropathic and microvascular complications and improve autonomic function. The effects of prior intensive versus conventional insulin therapy on the prevalence of cardiac autonomic neuropathy in former subjects of the DCCT (Diabetic Control and Complications Trial) have been evaluated.²³ DCCT autonomic measures (R-R variation with paced breathing, Valsalva ratio, postural changes in BP, and autonomic symptoms) were repeated in 1226 subjects studied 13 to 14 years after the end of the DCCT. Although the prevalence of cardiac autonomic neuropathy was higher in both groups after 13 to 14 years, the incidence was much lower (odds ratio, 0.69; 95% confidence interval, 0.51 to 0.96) in the former intensive group than in the conventional group, thus suggesting that the benefits of intensive insulin therapy in reducing the risk for autonomic neuropathy may be sustained for many years.²³ However, an analysis of the ACCORD (Action to Control Cardiovascular Risk in Diabetes) study suggested that even though cardiovascular autonomic neuropathy is associated with increased mortality in patients with type 2 diabetes, those with established cardiovascular autonomic neuropathy at baseline had similar

mortality outcomes from both intensive and standard glycemic treatment.²⁴

Amyloidosis can also result in secondary autonomic failure (see Chapter 65). A retrospective study of 65 patients who had biopsy-proven amyloidosis and also underwent autonomic function testing suggested that those with peripheral neuropathy of unknown origin should undergo autonomic testing, even in the absence of symptoms of autonomic failure.²⁵ Early recognition of autonomic failure in these patients may lead to earlier diagnosis of underlying amyloidosis and hence earlier treatment.

Other common causes of secondary autonomic failure include renal failure¹⁰ (see Chapter 88), paraneoplastic syndromes, and vitamin B12 deficiency. If antibodies against components of the autonomic nervous system are present in the absence of clinically apparent neoplasm, further assessment for neoplasm should be done given that clinical improvement can be achieved following treatment. Human immunodeficiency virus infection can cause autonomic dysfunction independent of effects on cardiac function (see Chapter 70), as can heavy metal intoxication, particularly with copper, lead, mercury, or thallium.

Autoimmune Autonomic Failure

Severe autonomic failure can result from autoimmune damage to neurons. Progression of disease is variable and ranges from days to years. Because of the variable time at which patients are initially evaluated, it may be difficult to separate autoimmune autonomic failure from other types of autonomic dysfunction. In addition to OH, bowel and bladder dysfunction may occur. Plasma catecholamine levels are usually low and rise minimally with standing. Some reports have shown the beneficial effect of intravenous gamma globulin. One case report has also suggested a role for plasma exchange pheresis in treatment.

In addition to autoimmune autonomic failure, autonomic dysfunction may be seen as a complication in severe cases of Guillain-Barré syndrome. In these patients, treatment is often supportive and orthostatic intolerance may be the only symptom. Furthermore, autonomic function may return completely with general motor function. Orthostatic intolerance may also occur as a sequela of prolonged bed rest in these patients.

Congenital Autonomic Failure

The first autonomic disorder associated with a defined genetic abnormality was dopamine beta-hydroxylase deficiency. Dopamine beta-hydroxylase converts dopamine to norepinephrine in vesicles in noradrenergic neurons. Thus, this is a disorder of sympathetic noradrenergic function. As a result of the norepinephrine deficiency, patients cannot mount a vasoconstrictor response to upright posture and have marked OH with a blunted rise in heart rate.¹ Also, they have excess quantities of dopamine, which is released in place of norepinephrine and results in increased urinary sodium excretion, ptosis, nasal stuffiness, joint hyperextensibility, and retrograde ejaculation in men. Dihydroxyphenylserine has been used with some benefit to restore norepinephrine levels because these patients have normal levels of dopa decarboxylase.

ORTHOSTATIC INTOLERANCE

Orthostatic intolerance (see Chapter 40) is an entity distinct from OH and only occasionally is characterized by the rapid development of OH. Generally, symptoms are seen in young women,

who report visual changes, poor concentration while standing, fatigue while standing, tremor, and often syncope. Several diseases are associated with orthostatic intolerance. These range from problems of localized excess noradrenergic stimulation to abnormalities in the baroreflex response. However, there is considerable overlap in terms of diagnosis, especially among postural tachycardia syndrome, neurally mediated syncope, and chronic fatigue syndrome, which often coexist in patients with orthostatic intolerance.

Postural Tachycardia Syndrome

Postural orthostatic tachycardia syndrome (POTS) is primarily characterized by orthostatic symptoms, tachycardia, and the absence of significant hypotension.²⁶ Symptoms of orthostatic intolerance include those elicited by brain hypoperfusion and by sympathetic excitation.²⁷ POTS affects females in a 5:1 ratio over males, and most patients are between 20 and 40 years of age. POTS is heterogeneous in mechanisms, as well as in clinical features. Major mechanisms are denervation (neuropathic POTS), deconditioning, and a hyperadrenergic state (Fig. 89-2). Each of these three major mechanisms is exacerbated by hypovolemia.

Diagnostic criteria for POTS are controversial and may be based on several criteria, including the following:

1. Orthostatic tachycardia greater than 30 beats/min, usually to a rate of 120 beats/min or higher
2. Transient decrease in SBP of more than 20 mm Hg, with recovery within the first minute of tilt

FIGURE 89-2 Examples of BP and heart rate recordings from a normal subject (top panel), a patient with neuropathic POTS (middle panel), and a patient with hyperadrenergic POTS (bottom panel). Note the modest reduction in BP in neuropathic POTS. Hyperadrenergic POTS is associated with prominent BP oscillations, an orthostatic increment in systolic BP, and a prominent norepinephrine response to head-up tilt. (From Low PA, Sandroni P, Joyner M, Shen W-K: Postural tachycardia syndrome. *J Cardiovasc Electrophysiol* 20:352, 2009.)

3. Standing plasma norepinephrine level higher than 600 pg/mL
4. Severe orthostatic symptoms

Although patients with POTS frequently have increased anxiety and somatic hypervigilance, the excessive tachycardia during orthostatic stress is not secondary to anxiety but is a physiologic response that helps maintain arterial pressure during venous pooling.²⁸ Patients with POTS also demonstrate excessive tachycardia during exercise, which does not appear to be secondary to abnormal baroreflex regulation of the heart rate.²⁹ Orthostatic intolerance is potentiated after deconditioning because of spaceflight or prolonged bed rest. It has been proposed that autonomic function is intact in POTS patients and that the marked tachycardia during orthostasis is due to a small heart coupled with reduced blood volume—"attributable to cardiac atrophy and hypovolemia."³⁰ Indeed, in this study, exercise training improved or even cured POTS in most patients.³⁰ Other treatment options for POTS include increasing intravascular volume with high levels of salt and fluids, supplemented by compression garments.²⁷ Pharmacologic interventions include low-dose beta blockers and low-dose vasoconstrictors such as midodrine and fludrocortisone. A randomized, crossover acute drug trial has compared low-dose (20-mg) propranolol with placebo and found that propranolol reduces supine and standing heart rates and improves symptoms at 2 hours after dosing.³¹ In a comparison between low-dose and a higher-dose (80-mg) propranolol, the higher dose had a great effect on attenuating the standing heart rate and orthostatic tachycardia, but the lower dose elicited greater improvement in symptoms 2 hours after dosing. The therapeutic importance of exercise training and improved physical conditioning is becoming increasingly apparent as an important strategy for deconditioned patients.

Neurally Mediated Syncope

Neurally mediated syncope, also known as neurocardiogenic syncope, is characterized by periodic syncopal episodes with normal autonomic function between episodes (Fig. 89-3; see Chapter 40). Patients frequently have vasovagal-like fainting and a reduction in vascular sympathetic activity during the syncopal episode. Several variants of neurally mediated syncope are discussed later in this chapter.

The mechanisms underlying neurally mediated syncope remain controversial but are presumed to be secondary to decreased venous return to the heart resulting from increased peripheral venous pooling of blood, which results in cardiac hypercontractility. Normal

flow-mediated dilation but potentiated nitrate-mediated dilation suggests possible vascular sensitivity to nitrates.³² One study has documented the complete disappearance of peroneal sympathetic nerve recordings during syncopal episodes in these patients. The hypercontractile response activates cardiac mechanoreceptors, which results in paradoxical reflex bradycardia and decreased systemic vascular resistance despite the already decreased venous return and thereby elicits the characteristic presyncopal symptoms of weakness, lightheadedness, feelings of warmth or cold, and ultimate brief loss of consciousness. This reflex bradycardia and hypotension are similar to those evoked by the Bezold-Jarisch reflex. In the absence of any underlying cardiovascular, neurologic, or other disease, isolated vasovagal syncope may represent a variation of normal; because spontaneous syncope is relatively common, subjects are generally normotensive with otherwise normal BP regulation,³³ and the long-term prognosis is usually excellent,³⁴ aside from sequelae of any falls that may occur with a syncopal event.

Potential cardiac causes of syncope must be considered before this diagnosis of exclusion can be made. However, even then the diagnosis can be difficult to make. Situational syncope must be excluded, as well as phobia syndromes or other organic causes. Tilt-table testing has good specificity but uncertain sensitivity in diagnosis and is not always reproducible. Implantable loop recorders, which store 45 minutes of retrospective electrocardiographic data, may also be used and can be activated by patients after each syncopal event. However, their cost is high and diagnostic benefit remains undefined.

Typically, treatment in these patients is conservative and involves education, particularly in determining potential predisposing factors and recognizing prodromal symptoms when they occur. Increasing fluid and salt intake may also help in avoiding the development of syncope. Pharmacologic therapy includes beta blockers, which presumably work via inhibition of mechanoreceptor activation; fludrocortisone, which expands central fluid volume via retention of sodium; and vasoconstrictors and selective serotonin reuptake inhibitors, which may have a role in regulating sympathetic nervous system activity. ISSUE-3 (Third International Study on Syncope of Uncertain Etiology) randomized patients 40 years and older with severe asystolic neurally mediated syncope to pacing versus no-pacing therapy.³⁵ In this double-blind study of 79 patients who underwent pacemaker implantation, those randomized to dual-chamber pacing experienced a 25% recurrence rate of syncope, whereas those randomized to "pacemaker off" had a 57% recurrence rate of syncope (Fig. 89-4). The overall absolute reduction in syncope

recurrence was 32% with dual-chamber pacing. Caveats include balancing the cost and complications of pacemaker placement against potential therapeutic benefit. Furthermore, although cardiac pacing addresses the bradycardia, it may be incompletely effective because it does not compensate for the vasodepressor component in patients with predominantly vasodepressor (versus asystolic) neurally mediated syncope.

Chronic Fatigue Syndrome

Chronic fatigue syndrome is characterized by new, unexplained fatigue that lasts for at least 6 months, is unrelieved by rest, and has no clear cause. The cause of this syndrome is unclear. Some data have implicated impairments in skeletal muscle and cardiac muscle metabolism and bioenergetics.³⁶ Other studies have suggested that dysautonomia may be common in patients with chronic fatigue syndrome. On the basis of tilt-table testing, more than 60% of patients with chronic fatigue show abnormal BP or

FIGURE 89-3 Recordings of sympathetic nerve activity and BP before and during vasovagal syncope. Note the simultaneous reductions in sympathetic nerve activity, heart rate, and BP associated with the episode of syncope (*). pleth = plethysmography; Symp = sympathetic. (From Wallin BG, Sundlof G: Sympathetic outflow to muscles during vasovagal syncope. *J Auton Nerv Syst* 6:287, 1982.)

FIGURE 89-4 Time to first recurrence of syncope according to the intention-to-treat analysis. The probability value was calculated at the threshold of statistical significance of 0.04. Pm = pacemaker. (From Brignole M, Menozzi C, Moya A, et al: Pacemaker therapy in patients with neurally mediated syncope and documented asystole: Third International Study on Syncope of Uncertain Etiology [ISSUE-3]: A randomized trial. *Circulation* 125:2566, 2012.)

heart rate responses, with sudden hypotension or severe bradycardia or tachycardia occurring along with decreased consciousness. Syncope episodes in these patients are usually associated with a decrease in sympathetic outflow in the absence of ventricular hypovolemia or hypercontractility.

Patients with chronic fatigue have not been shown to benefit from treatment with fludrocortisone and high salt intake, unlike most patients suffering from orthostatic intolerance secondary to sympathetic neurocirculatory failure. Thus the exact mechanism of orthostatic intolerance in these patients is not known. Alternative treatments may include midodrine or beta-adrenoreceptor blockers. Whether relief of any dysautonomic symptoms in these patients may relieve the symptoms of fatigue is unclear. Because these patients are often physically inactive, an exercise conditioning program implemented to improve well-being may help alleviate the symptoms.

Baroreflex Failure

Causes of baroreflex failure most often include surgery, radiation therapy, and cerebrovascular accidents. Failure results from damage to afferent neuronal input (via the vagus and glossopharyngeal nerves) or from damage to brainstem nuclei or interneurons.¹ As a result, there is a loss of response to arterial baroreceptor stimulation.

These patients are frequently seen acutely with significant pheochromocytoma-like pressor crises associated with palpitations, diaphoresis, and severe headaches. Patients may initially be encountered after surgical intervention, trauma, or stroke. BP is labile and may rise to extremely high levels. Some studies have shown that 9% to 30% of patients exhibit hypertension consistent with baroreflex failure after carotid endarterectomy.¹ Patients with unilateral involvement may show almost complete failure as well. The right carotid baroreflex may be more effective than the left carotid reflex, thus suggesting a difference in clinical outcome depending on which carotid artery is affected.

The clinical findings can vary over time, and acute episodes during waking hours may mimic pheochromocytoma; severe hypotension and bradycardia may occur during sleep. The heart rate and BP change together (concomitant rises or falls in both). Furthermore, little or no OH occurs initially, but it may appear later with prolonged standing. Apneic episodes may occur because of loss of neural afferents from carotid chemoreceptors.

Loss of the baroreflex buffering mechanism results in prolonged and exaggerated responses to a variety of tests, such as the cold

pressor test. Plasma and urinary norepinephrine levels may be high, with plasma levels in the 1000- to 3000-pg/mL range. Minor stimuli can result in pressor crises, even after successful initial treatment in these patients, and long-term therapy may be necessary. Diagnostically, patients may show a depressor response to a small dose of clonidine but no heart rate response to depressor or pressor infusions even though the heart rate will change with sedation or cortical stimuli.¹

Initial therapy over the first 72 hours can include nitroprusside and clonidine. Chronically, patients may continue to have labile hypertension and tachycardia alternating with hypotension and bradycardia. This may be treated effectively with clonidine and methyldopa. During periods of excess cortical stimulation (e.g., stress, anxiety), low-dose benzodiazepines and clonidine may help relieve the symptoms.¹

Carotid Sinus Hypersensitivity

Carotid sinus hypersensitivity is defined as a ventricular pause longer than 3 seconds and/or a fall in SBP of greater than 50 mm Hg with carotid sinus massage.³⁴ Baroreflex sensitivity is increased in both asymptomatic and symptomatic patients with carotid sinus hypersensitivity.³⁷ Carotid sinus syndrome refers to the association of carotid sinus hypersensitivity with spontaneous syncope. Carotid sinus massage should be avoided in patients with previous transient ischemic attacks, stroke within 3 months, or carotid bruits unless Doppler studies exclude significant carotid artery disease. Cardiac pacing has been considered as a therapeutic option, although a randomized, double-blind, placebo-controlled crossover trial did not show any benefit of dual-chamber pacing³⁸ (see Chapter 36).

Norepinephrine Transporter Deficiency

Patients with norepinephrine transporter deficiency have a deficiency of the membrane norepinephrine transporter. As a result, there is more than a 98% reduction in reuptake of norepinephrine at the sympathetic nerve ending. This results in elevated levels of norepinephrine at the synapse and resultant tachycardia, especially on standing, when norepinephrine delivery is increased despite the already elevated synaptic concentration.

Addison Disease

Adrenal hypofunction, Addison disease, and particularly addisonian crisis may be manifested as a global autonomic dysfunction, with particular impact on the heart rate and BP. The combined glucocorticoid and mineralocorticoid deficiency may be caused by a defect anywhere in the hypothalamic-pituitary-adrenal axis. Glucocorticoid insufficiency contributes to hypotension and may reduce myocardial contractility. In primary Addison disease, mineralocorticoid insufficiency disturbs the renin-angiotensin-aldosterone axis and intravascular fluid balance, thus contributing to the hypotension and tachycardia seen in these patients. The combined effects of glucocorticoid and mineralocorticoid deficiency lead to decreased intravascular volume with an attenuated cardiac response to stressors and therefore result in OH and eventually circulatory collapse without appropriate treatment. Thus, Addison disease can mimic central autonomic dysfunction because of its effects on circulatory control and volume status.

VARIANTS OF NEUROCARDIOGENIC SYNCOPES

Aortic Stenosis

Exertional syncope is common in patients with aortic stenosis (see Chapter 63) and has often been attributed to carotid sinus hypersensitivity, arrhythmias, or left ventricular failure. The normal compensatory response to exercise involves a rise in BP and heart rate

as a result of an increase in cardiac output, peripheral vasoconstriction in inactive muscles, and vasodilation in active muscles. The onset of near-syncope in patients with aortic stenosis has been associated with a large reduction in BP and cardiac output to resting levels in the absence of appropriate reflex vasoconstriction. Paradoxical forearm vasodilation during leg exercise develops in patients with aortic stenosis and a history of exertional syncope. This muscular vasodilation is presumed to be caused by activation of mechanosensitive vagal afferents in response to an outflow obstruction—associated increase in left ventricular end-diastolic pressure. The net effect of this process is a reflex vasodilation. However, the vasodilator response is not accompanied by bradycardia, thus suggesting that the syncopal response to exertion in aortic stenosis is primarily vasodepressor rather than cardioinhibitory in nature.

Renal Failure and Hemodialysis

Acute hypotension is a common complication of hemodialysis, although the precise cause is poorly defined (see Chapter 88). Presumably, the mechanism may be similar to that of hypotension associated with acute hemorrhage, in which there is paradoxical sympathetic withdrawal, vasodilation, and bradycardia. This appears to result from activation of cardiac vagal afferents caused by tachycardia and decreased ventricular filling. Hypotension-prone hemodialysis patients initially have tachycardia, sympathetic activation, and vasoconstriction, followed by profound hypotension caused by paradoxical bradycardia, vasodilation, and sympathetic inhibition. This is different from patients not prone to hypotension, who exhibit progressive rises in heart rate and sympathetic activity during dialysis. Furthermore, there is a clear difference in cardiac adaptation to changes in fluid volume, with hypotension-prone patients exhibiting a progressive reduction to almost obliteration of left ventricular end-systolic dimensions and hypotension-resistant patients exhibiting little change. This suggests that the mechanism whereby hypotension develops in hypotension-prone hemodialysis patients may be via excessive myocardial contraction around an empty chamber, which results in activation of ventricular mechanoreceptors and consequent cardiac inhibition. The differential diagnosis of hypotension during dialysis should also include simple hypovolemia, pericardial effusion with the development of tamponade as cardiac filling pressures decrease, and cardiac ischemia.

Right Coronary Thrombolysis

Patients with right coronary artery occlusion following intracoronary thrombolytic therapy and resultant reperfusion exhibit a greater incidence of bradycardia and hypotension ($\approx 80\%$) than do patients with left coronary occlusion ($\approx 14\%$; see Chapter 55). This perceived difference may be caused in part by the preferential distribution of inhibitory cardiac receptors in the inferoposterior wall of the ventricle. Activation of the inhibitory reflex may be caused by sudden improvement in contractile force of the previously akinetic segment of myocardium, which results in the activation of mechanosensitive vagal afferents, or by the release of free radicals and other metabolic products, which results in the activation of chemosensitive vagal afferents.

Inferior Wall Myocardial Infarction

As noted, inhibitory cardiac receptors are preferentially located in the inferoposterior wall of the left ventricle. With infarction, there would be an expected reflex tachycardia, and this is often the case in patients who suffer from an anterior wall infarction. However, patients suffering from an inferior wall infarction (see Chapter 52) may have a relatively increased incidence of bradycardia and hypotension. During Prinzmetal angina, spasm of vessels supplying the inferior wall more often results in bradycardia than does spasm of vessels supplying the anterior wall, which more often results in tachycardia. This reflex activation of cardiac inhibitory signals also appears

to result in inhibition of renal sympathetic activity, hence further potentiating neurogenic hypotension.

A reflex reduction in cardiac afterload and heart rate may be beneficial in the context of myocardial infarction caused by a decrease in myocardial oxygen demand. Thus, low-grade activation of the cardiac inhibitory reflex may conceivably contribute to the more favorable prognosis associated with inferior wall myocardial infarction.

Hypertrophic Obstructive Cardiomyopathy

Syncope in patients with hypertrophic obstructive cardiomyopathy (HCM) is associated with a high risk for sudden death (see Chapter 66). In these patients, sudden death has generally been associated with a tendency for the development of malignant arrhythmias. However, patients with HCM also demonstrate syncope during sinus rhythm and an abnormal BP response to exercise, thus suggesting that activation of left ventricular baroreceptors may cause the associated hypotension and hemodynamic collapse. The predisposition to hypotension and bradycardia in these patients appears to result from the activation of left ventricular mechanoreceptors. Studies involving tilt-table testing in such patients resulted in hypotension in a significant number of those with a previous history of syncope. Head-up tilt was paired with echocardiography, which revealed reduced cavity sizes and increased fractional shortening with head-up tilt, consistent with conditions that would be favorable to the activation of left ventricular mechanoreceptors. This suggests that the cause of syncope in patients with HCM may not just be malignant arrhythmias but that it may also occur because of inappropriate activation of inhibitory left ventricular mechanoreceptors in response to vigorous ventricular contraction or reduced ventricular cavity size.

Blood Phobia

Many people suffer from blood or injury phobia and experience syncope or presyncope in response to these visual stimuli. Syncope in these patients has been thought to be largely neurogenic and anticipatory in origin because of the high correlation with situational stressors. It has been suggested that patients suffering from syncope secondary to blood or injury phobia actually have an underlying predisposition to neurocardiogenic syncope. Patients with a history of blood phobia-induced syncope have been shown to have a higher rate of tilt-induced syncope than controls do. These findings suggest that fainting in response to blood or injury may be caused by dysfunction of neural circulatory control and has an associated organic origin. It has been proposed that this dysfunction may secondarily lead to the phobia because of repeated syncopal events.

DISORDERS OF INCREASED SYMPATHETIC OUTFLOW

Increased sympathetic outflow may occur in a number of diseases, either as a primary event contributing to development of the disease or as secondary to the underlying disease. Sympathetic activation increases with age, even in the absence of disease,³⁹ and can contribute to the age-related increased risk for hypertension. Although women have lower muscle sympathetic activity than men do, their age-related rise in sympathetic drive is greater, so the difference in sympathetic activation between men and women is attenuated by menopause.

Neurogenic Essential Hypertension

Patients with early essential hypertension (see Chapter 43) may have a hyperdynamic circulation driven by increased firing of efferent sympathetic nerves to skeletal muscle and elevated levels of norepinephrine in the heart and kidneys. High sympathetic outflow may be secondary to one or more of the following: impaired baroreflex gain, increased chemoreflex gain, insulin resistance, and genetic

factors. Sympathetic activation stimulates the heart with consequent elevation of cardiac output, neurally mediated vasoconstriction, and augmentation of renin secretion and tubular reabsorption of sodium, thereby increasing total-body fluid volume. In the long term, secondary end-organ and vascular changes may sustain established hypertension, even in the absence of overt sympathetic activation and tachycardia.

Recent studies have suggested that catheter-based radiofrequency ablation of renal nerves (efferent sympathetic and afferent sensory) bilaterally in patients with resistant hypertension may elicit significant and sustained (up to 12 months after the procedure) reductions in systolic and diastolic pressure.⁴⁰ In a recent case study, bilateral renal sympathetic nerve ablation was accompanied by marked falls in renal sympathetic activity, a decrease in renin activity by 50%, reduced whole-body norepinephrine spillover, increased baroreflex gain, and a decrease in BP.⁴¹ At 12 months after the procedure, BP remained significantly lower, microneurography showed reduced sympathetic activity, and cardiac MRI showed a decrease in left ventricular mass (Fig. 89-5).

Sympathetic inhibition induced by stimulation of the carotid baroreceptor may also have a role in reducing BP, especially in patients with resistant hypertension.⁴² In a group of 12 subjects with resistant hypertension, a bilateral electric baroreflex stimulator at the level of

the carotid sinus (Rheos) acutely decreased BP by reducing central sympathetic outflow⁴² (Fig. 89-6). In the subsequent double-blind Rheos Pivotal Trial,⁴³ 265 patients with resistant hypertension were implanted with the Rheos device and a month later were randomized (2:1) to baroreflex activation therapy (BAT) (group A) or BAT delayed until the 6-month visit (group B). The acute SBP responder rate at 6 months was not significantly different (54% for group A and 46% for group B), but 42% of group A and 24% of group B achieved an SBP of less than 140 mm Hg at 6 months ($P = 0.005$). Further trials are needed to more fully establish the role of BAT in patients with resistant hypertension.

Panic Disorder

Cardiovascular events during a panic episode may be triggered by increased sympathetic outflow (see Chapter 86). Although the true risk is unknown, it seems that there may be some increased ischemic heart disease in patients with a history of panic disorder. During a panic attack, sympathetic nerve firing increases, as does adrenomedullary secretion of epinephrine. Patients who describe angina pectoris-like symptoms during a panic attack may or may not have electrocardiographic changes consistent with myocardial ischemia. It has been suggested that some patients may experience angina-like attacks secondary to coronary artery spasm.

Coronary Artery Disease

Sympathetic activity is increased in unstable angina and after a myocardial infarction³⁹ (see Chapter 51). The heightened sympathetic drive may persist for 6 to 9 months and may be implicated in subsequent cardiovascular morbidity and mortality.

Congestive Heart Failure

A failing heart becomes partly sympathetically denervated (Fig. 89-7; see Chapter 24). Thus, historically, adrenergic agonists were used to treat these patients, although this turned out to be more dangerous than helpful. In fact, beta blocker use in these patients contributed to long-term improvement rather than worsening of heart failure. The reason for this may be partially due to the fact that despite the low myocardial tissue concentration of norepinephrine, cardiac norepinephrine spillover is increased to levels associated with near-maximal aerobic exercise. Heart failure patients may also exhibit baroreflex and chemoreflex dysfunction and disrupted heart rate variability and ventilatory control. In patients with dilated cardiomyopathy, the presence of sleep apnea may further increase cardiac sympathetic activation,⁴⁴ perhaps because of heightened central chemosensitivity.⁴⁵ Increased cardiac sympathetic activation, altered baroreflex gain, chemoreflex dysfunction, blunted heart rate variability, and disordered breathing control have been associated with poorer long-term outcomes. It has been proposed that the development of heart failure and an increase in

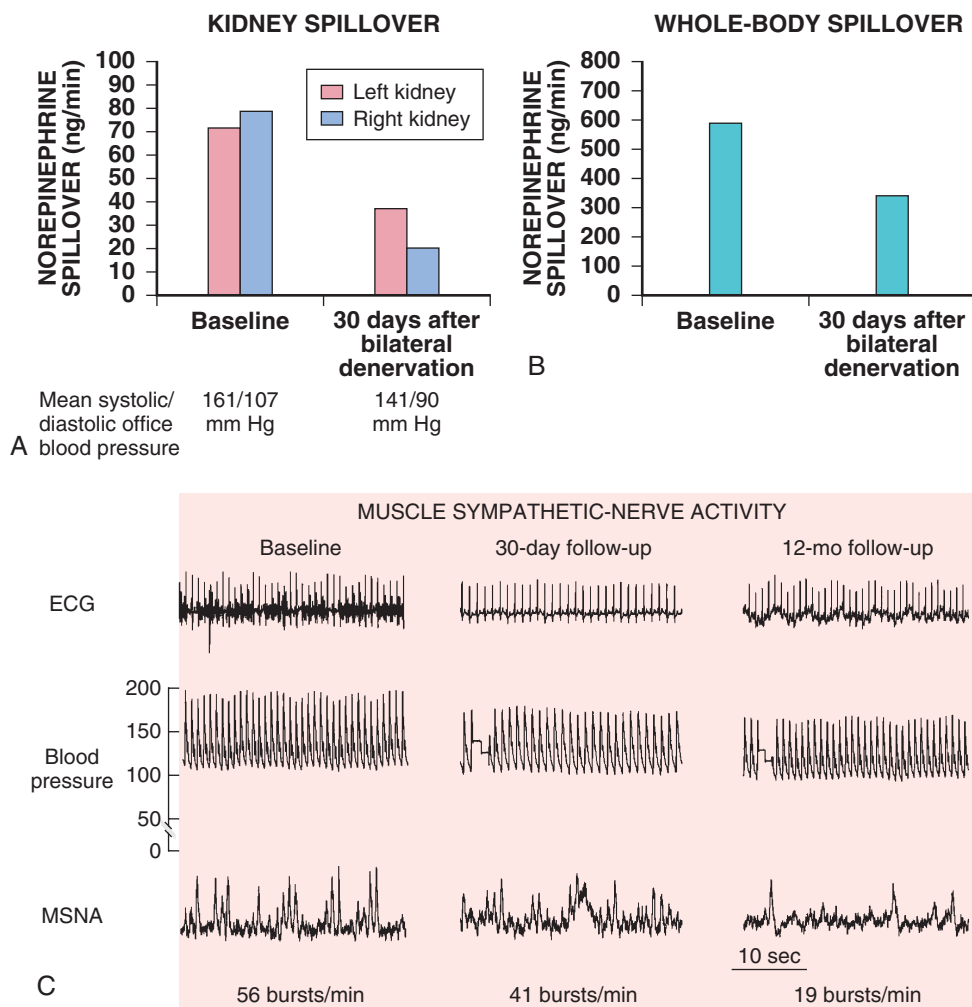

FIGURE 89-5 Norepinephrine renal and whole-body spillover and results of microneurography before and after renal nerve ablation. **A**, Results of bilateral renal denervation, as assessed by the radiotracer dilution method, at baseline and 30 days after the procedure. After ablation, decreases in renal norepinephrine spillover were observed in both kidneys (48% in the left kidney and 75% in the right kidney), thus indicating substantial modulation of renal sympathetic efferent nerve activity after the procedure. Simultaneously, a marked reduction in whole-body sympathetic nerve activity was apparent, with a decrease in whole-body norepinephrine spillover of 42% (**B**). **C**, Reduction in muscle sympathetic nerve activity (MSNA), as assessed in the peroneal nerve on microneurography, after bilateral renal nerve ablation, which highlights the possibility that inhibition of afferent renal nerve activity may contribute to a reduction in central sympathetic drive. (From Schlaich MP, Sobotka PA, Krum H, et al: Renal sympathetic-nerve ablation for uncontrolled hypertension. *N Engl J Med* 361:932, 2009.)

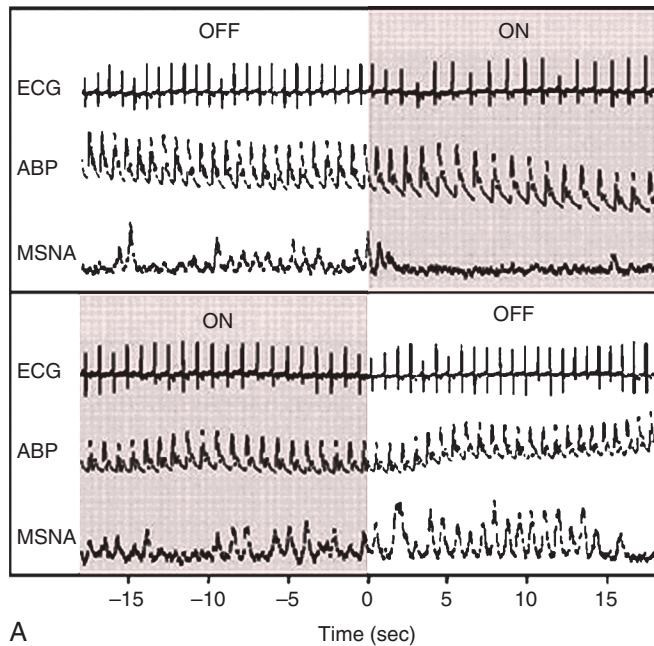

FIGURE 89-6 A, Original recordings showing arterial blood pressure (ABP) and muscle sympathetic nerve activity (MSNA) recordings in patient 9. When the stimulator was switched on (**upper panel**), ABP and MSNA acutely decreased and remained decreased during 9 minutes of continued stimulation. After this period the stimulator was switched off (**lower panel**), ABP and MSNA returned to baseline levels. **B**, Mean responses showing average ABP, heart rate (HR), and MSNA responses in patient 9 over six cycles of alternating stimulation. During each cycle the stimulator remained off for 9 minutes and was then switched on for 9 minutes. au = arbitrary units. (From Heusser K, Tank J, Engeli S, et al: Carotid baroreceptor stimulation, sympathetic activity, baroreflex function, and blood pressure in hypertensive patients. *Hypertension* 55:619, 2010.)

sympathetic outflow may occur in conjunction with and feed off one another to further affect cardiac status adversely. Although cardiac transplantation may improve some of the autonomic disturbances seen in heart failure, residual autonomic dysfunction may persist.

Obstructive Sleep Apnea

An increase in sympathetic outflow takes place during both sleep and waking hours in patients with OSA (see Chapter 75). This is in part caused by the hypoxemia and hypercapnia that occur during apneic episodes. During waking hours, the increased sympathetic outflow may be related to increased tonic chemoreflex sensitivity. Most patients with OSA are also obese, and the interaction between obesity and OSA in increasing sympathetic activity awaits further clarification. Continuous positive airway pressure treatment during sleep appears to attenuate the sympathetic outflow, even during daytime wakefulness.

Pheochromocytoma

Pheochromocytoma is a rare catecholamine-secreting tumor derived from the chromaffin cells of the adrenal gland or the paraganglion chromaffin tissue of the sympathetic nervous system (see Chapters 43 and 81). Most commonly, these tumors arise from the adrenal glands, but it is also possible for extra-adrenal pheochromocytomas to develop in the sympathetic ganglia anywhere from the brain to the bladder. Because of the increased secretion of catecholamines, excess sympathetic drive occurs and results in life-threatening hypertension or cardiac arrhythmias. The excess secretion is associated with lack of normal innervation to the adrenal medulla. Pheochromocytomas may also be sporadic or familial, with primarily norepinephrine secretion in the former and epinephrine secretion in the latter. Diagnosis requires testing for plasma metanephrine, which has a higher sensitivity and lower specificity, and 24-hour urine collection for total catecholamines, vanillylmandelic acid, and metanephrines, which has higher specificity and lower sensitivity. Computed tomography of the abdomen and pelvis is the typical imaging modality used but is neither the most sensitive nor the most specific, particularly for adrenal tumors smaller than 1 cm. MRI has almost 100% sensitivity for the detection of adrenal pheochromocytomas. When clinical suspicion is high because of positive laboratory test results but imaging reveals no source, a ¹³¹I-MIBG scan may be useful. Definitive treatment is via surgical resection with appropriate alpha and beta blockade preoperatively.

Stroke

Cerebral autoregulatory changes may also influence neural circulatory mechanisms, such as baroreflex sensitivity,⁴⁶ thus suggesting that stroke may induce significant abnormalities in autonomic control. Indeed, in patients with middle cerebral artery infarction, the presence of decreased baroreflex sensitivity, suggestive of sympathetic activation, was associated with a malignant course and the development of life-threatening edema, probably secondary to sympathetic hyperactivity.⁴⁷ In stroke patients, autonomic cardiovascular dysfunction is common, with evidence of sympathetic dominance.⁴⁸ National Institutes of Health Stroke Scale (NIHSS) scores correlate with autonomic dysfunction after stroke, thus potentially providing a predictive measure to help in the early diagnosis of autonomically mediated poststroke complications.⁴⁸

Sleep-Associated Disorders

In general, parasympathetic tone increases during non-rapid eye movement (REM) sleep. This is associated with a fall in the heart rate during sleep. However, REM sleep, which is predominant in the later hours of sleep, just before waking, may be associated with significant sympathetic activation.⁴⁹ This may be relevant to nocturnal angina associated with REM and to the predominance of cardiac

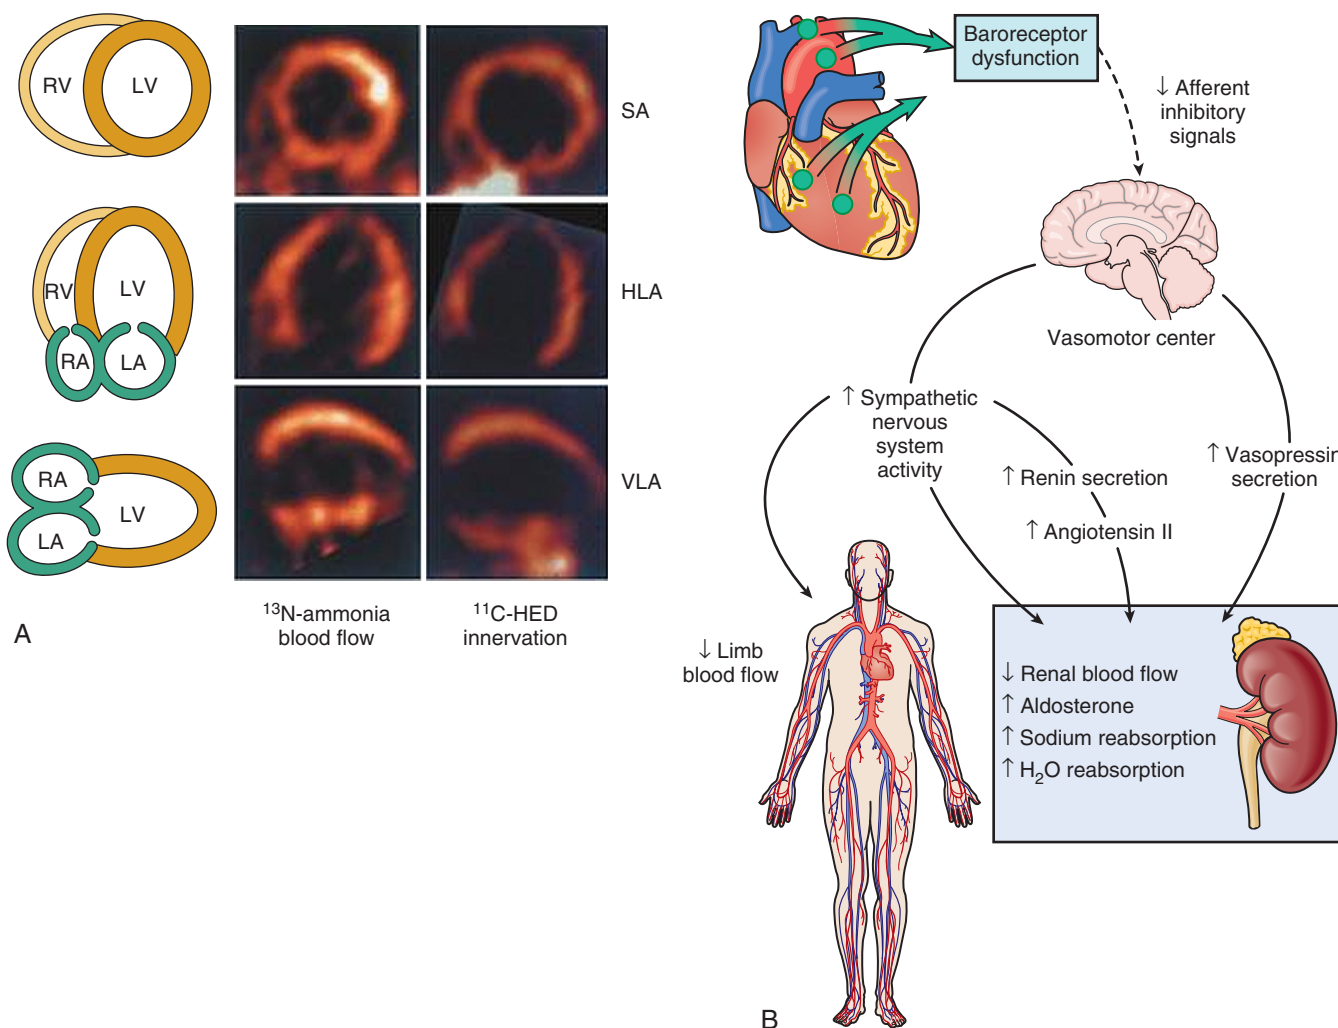

FIGURE 89-7 A, Autonomic denervation of the failing heart. Positron emission tomography images obtained from patients with congestive heart failure (CHF) demonstrate that partial denervation of the left ventricle is present in these patients. The images above demonstrate the short-axis (SA), horizontal long-axis (HLA), and vertical long-axis (VLA) views of the heart. Ammonia uptake is seen to be relatively homogeneous, which is consistent with intact myocardial perfusion. C-11 hydroxyephedrine (C-HED) uptake marks innervation of the heart, and patients with heart failure have reduced retention that appears to be relatively heterogeneous, thus suggesting partial denervation of the left ventricle. A known association exists between the extent of denervation and clinical outcome, with higher degrees of denervation being correlated with increased mortality. Denervation of the heart may affect cardiac and vascular control secondary to defective afferent autonomic input from mechanoreceptors in the left ventricle. **B**, Increased sympathetic activity in CHF. Baroreceptor dysfunction may partly account for the increased sympathetic activity seen in patients with CHF. Baroreceptor function is impaired in heart failure, in part because of partial sympathetic denervation of the heart. Thus, inhibitory input from cardiac mechanoreceptors is decreased despite increased intracardiac volumes. Typically, stimulation of these mechanoreceptors via increased stretch will result in vasodilation and depression of renal sympathetic nerve activity. However, because of partial denervation, there is a lack of appropriate inhibition of the sympathetic nervous system that leads to excessive sympathetic activity to the kidney, worsening fluid retention, and in peripheral blood vessels, potentiation of vasoconstriction. Therefore, partial denervation of cardiac mechanoreceptors may result in a neural circulatory profile mimicking that seen in hypovolemia and may, in part, explain the sympathetic activation and fluid retention seen in heart failure. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle. (**A**, from Schwaiger M, Bengel F: *Atlas of Heart Diseases: Nuclear Cardiology*. In Dilsizian V, Narula J, Braunwald E [series eds]. Philadelphia, Current Medicine, 2006; **B**, modified from Nohria A, Cusco J, Creager M: *Atlas of Heart Diseases: Heart Failure*. In Colucci WS, Braunwald E [series eds]. Philadelphia, Current Medicine, 2004.)

events during the early waking hours following sleep. Although parasympathetic activity largely dominates sleep, the increase in sympathetic outflow during REM sleep, when dreams are most likely to occur, may conceivably contribute to tachycardia and cardiac ischemia.

DISORDERS OF INCREASED PARASYMPATHETIC TONE

Increased parasympathetic tone can be associated with a number of physiologic and pathologic conditions, including weight loss and spinal cord trauma. Bradycardias, such as Mobitz type I heart block occurring during sleep, may also be caused by abrupt but physiologic increases in parasympathetic tone during REM sleep⁴⁹

(see Chapter 37). Also, the decrease in resting heart rate seen in well-conditioned athletes may be associated with elevated parasympathetic outflow at rest. However, in general, pathologic disorders of sympathetic outflow are more common than those of parasympathetic tone.

Sinus Arrhythmia

Under normal circumstances, the heart is under parasympathetic dominance. Variations from the resting state occur with each breath because of the influence of breathing on the flow of sympathetic and vagal activity to the sinoatrial node. With inhalation, vagus nerve activity is inhibited and the heart rate begins to increase. With exhalation, this process reverses. This variation in heart rate with breathing is normal and a sign of cardiac health. Absence of change in heart rate with inspiration suggests cardiac disease and disturbed or diseased neural circulatory control (see Chapter 37).

FUTURE PERSPECTIVES

Dysautonomias and other autonomic disorders can be debilitating and are often difficult to treat. Challenges in diagnosing and treating autonomic disorders include the ubiquitous nature of the autonomic nervous system, difficulties in differentiating autonomic symptoms from those caused by emotional or psychological disorders, relative paucity of quantitative measurements of autonomic dysfunction, and difficulties in accessing and modulating autonomic neural control. For example, evaluation of cardiac sympathetic innervation requires expensive imaging techniques or invasive measures of cardiac norepinephrine spillover, and cardiac vagal activation is usually extrapolated from measures of heart rate control.

Technologies for inexpensive, noninvasive, and accurate measures of human autonomic tone are sorely needed to advance diagnosis and therapy. The immunologic mechanisms underlying sympathetic activation and vascular consequences such as neurogenic hypertension may provide important avenues for therapeutic intervention.⁵⁰ Improvements in information technology and rapid signal acquisition and processing are already forming the foundation for acutely responsive software and hardware that can sense hemodynamic changes and respond in quick but measured fashion (e.g., could be enabled by an artificial baroreflex or implanted cardiac or vascular assist device). These could mimic autonomic function by modulating BP via pharmacologic intervention (infusion of vasoactive agents) or by triggering physical maneuvers, as needed.

Recent insights into the role of autonomic innervation of the heart and great vessels and the usefulness of ablation in treating tachyarrhythmias have also renewed interest in cardiac ganglia and their role in potentiating or inhibiting cardiac electrical instability.⁵¹ As methods are developed for accessing these ganglia safely in humans, it is likely that therapeutic innovations will emerge that are based on perturbing or inhibiting their structure and function.

Disclosure Index

The following contributors have indicated that they have a relationship which, in the context of their participation in the writing of a chapter for the tenth edition of *Braunwald's Heart Disease*, could be perceived by some people as a real or apparent conflict of interest,

but they do not consider that it has influenced the writing of their chapter. Codes for the disclosure information (institution[s] and nature of relationship[s]) are provided below.

RELATIONSHIP CODES

A—Stock options or bond holdings in a for-profit corporation or self-directed pension plan
B—Research grants
C—Employment (full or part-time)

D—Ownership or partnership
E—Consulting fees or other remuneration received by the contributor or immediate family

F—Nonremunerative positions, such as board member, trustee, or public spokesperson
G—Receipt of royalties
H—"Speaker's bureau"
